WHAT SHALL WE DO WITH THE CONSUMPTIVE POOR.*

By S. A. KNOPF, M.D.,
NEW YORK.

IN an audience of charity workers, largely composed of laymen, it goes without saying that I shall not attempt to answer this question from a purely medical point of view. What we are anxious to know is how we can help in the solution of the tuberculosis problem in its sociological aspect. Yet it seems to me essential that those of us who labor, not only with tuberculous patients, but also with their friends and relatives, and the large portion of the community whose sympathy we desire to enlist in our cause, should know the true status of a consumptive. We must make a concise, correct, and just idea of what kind of a malady pulmonary tuberculosis, or consumption, really is in order to combat it successfully as a social disease, that is to say, a disease of the masses. Permit me, therefore, to summarize our present knowledge in this respect, and to state the basis on which a trained and scientific charity organization should work.

We now know that tuberculosis, especially in its pulmonary form, is an infectious and *communicable* disease. I lay stress upon the word communicable, for I do not classify pulmonary tuberculosis with the dangerous contagious diseases, and I shall give briefly my reasons for not doing so. It is my firm conviction, based on the experiences and experiments of our greatest European and American scientists, such as Koch, Straus, Grancher, Prudden, Biggs, and others, and on a somewhat extensive experience of my own, that tuberculosis is not a dangerous contagious disease, but only a communicable one. To be in contact with a tuberculous individual who takes care of his expectorations or other secretions, which may contain the bacilli, is not dangerous. In sanatoria for consumptives, where the precautions concerning the sputum are most strictly adhered to, one is perhaps safer from contracting tuberculosis than anywhere else. The great danger from infection lies in the indiscriminate deposit of sputum containing the bacilli, which, when dry and pulverized, may be inhaled by susceptible individuals and then cause the disease to be developed. The communication of the germ of the disease is, however, less obscure to us in its process, and far more easily guarded against than the contagion arising from such maladies as diphtheria, scarlet fever, or smallpox. What has just been said concerning the absolute security from infection in a well-kept sanatorium cannot very well be said of a smallpox hospital, no matter how well directed the hygienic precautions may be. Against the danger from contracting smallpox we have thus far no other means than preventive vaccination, and, in case of an outbreak of the disease, the most rigid isolation. It is entirely different with tuberculosis. The simple contact of a smallpox patient may suffice to convey the disease. This is never possible with a consumptive, even should he be careless or unclean. To the average individual a prolonged exposure is necessary to the transmission of the disease. Herein lies the difference between communicable and contagious.

If pulmonary tuberculosis should be a dangerous contagious disease, as the authorities in the United States Marine Hospital Service would wish us to consider it, scientific charity workers would be powerless to do anything toward the solution of the problem, which is as much a social as it is a medical one. They would not dare to enter the homes of these unfortunate ones to bring them comfort, consolation, and relief. From the admirable paper of Dr. George F. Kean of Providence, R. I., and that of Dr. Lyle of Cincinnati read at a previous meeting of this conference, and from the articles of other authors on the subject which have appeared in the official organ, *Charities*, edited by Dr. Edward T. Devine of New York, you have learned why tuberculosis should be considered a decidedly preventable, and in many instances, absolutely curable disease. It is now also almost universally known to the medical profession, as well as to many of the laity, that tuberculosis in its pulmonary form can be cured in nearly all climates where the extremes of temperature are not too pronounced, and where the air is relatively pure and fresh. In other words, it is not always necessary for a consumptive patient to travel long distances and seek special climatic conditions. In most instances he has a chance of getting well even in his home climate. The sooner the patient puts himself under the care of a competent physician the greater are his chances of recovery. The well-trained physician is the most competent person to guide the patient in the way to prevent reinfection of himself or the infection of his fellowmen. The most modern and most successful methods of treating consumption consist solely and exclusively in the scientific and judicious use of fresh air, sunshine, water, abundant and good food, and the help of certain medicinal substances when the just-mentioned hygienic and dietetic means do not suffice in themselves to combat the disease. The thorough and constant supervision of the pulmonary invalid, the immediate intervention when new symptoms manifest themselves or old ones become aggravated or do not disappear rapidly enough, the prescription of proper food and drink can only be had at the hands of the thoroughly trained physician in the patient's home, or in a well-equipped sanatorium constructed specially for that purpose.

In how many cases which come under our observation can we provide the most modern and most successful methods of treating consumption? From the experience I have had myself as a medical worker among the consumptive poor, I should venture to say that we come in contact with three classes of consumptives, and each class, to my mind at least, needs our assistance as urgently as the others. Of these three classes the first are the absolutely poor, with or without medical attendance, who come for help. The second class are those absolutely poor and consumptive persons whom we meet by chance and whose material need we discover at a glance; lastly, those who cannot be called absolutely poor, who earn enough from day to day so as not to be in want, but who are too proud to appeal for aid when ill, and would rather labor until they are carried home exhausted and put to bed, which they probably never leave again.

---

*Address delivered by invitation before the National Conference of Charities and Correction, at the meeting in Detroit, June 2, 1902.

What shall we do with the first class, the absolutely poor, who live in the crowded, unclean, badly-lighted and badly-ventilated tenement houses? What is the friendly visitor to do when he comes face to face with a family in want, of which the father, mother, or one of the children, who may be the breadwinner, is ill in bed with consumption?

If there are in the city, among whose poor you work, enough hospital facilities, the first thing would be the removal of the sufferer to the nearest consumptive hospital, removal from the sad, dark, and dreary surroundings, in which the poor consumptive constitutes a permanent center of infection, and where he has no possible chance of improvement, much less of cure. The next duty would then be to inform the sanitary authorities that they should disinfect and renovate the rooms occupied by this family, and the third duty would, probably, be to provide them with food and clothing until such a time as the breadwinner shall return to them, ready to take up again the support of the family. If he dies, the family will probably remain a burden to the community until the children become, in turn, breadwinners. With the second class of consumptives, with whom we come in contact accidentally, but whose social and physical conditions are the same, we could not, nor would we wish to, act differently. Then comes the third class, that is to say, the not-absolutely poor, who work until they can work no longer. This class has always seemed to me particularly pathetic, just as interesting, and just as much in need as the one which applies directly for help to the Bureau of Charities.

It has been my privilege to see, among this class of patients, men and women who were veritable heroes. An example is the honest laborer, who has had the misfortune to become tuberculous, and finally phthisical, who, at the onset of the disease, had sought the advice of a physician. Presuming that a correct diagnosis had been made, the doctor most likely prescribed, with some tonic and codliver oil, also a few weeks' rest. This treatment, under the most favorable circumstances, meant the sacrifice of a good part of the savings of better days. After a while the patient, seemingly improved, resumed his former occupation, but the improvement was not lasting. He was again and again obliged to take a rest; the intervals between the periods of work became longer and longer; there were no more visits to the doctor. Occasionally, the nearest dispensary was visited, but, owing to the steady decrease of the little reserve fund, there must not only be economy in regard to the physician's visits, but also in the diet. Private, as well as dispensary physicians, urged that the food should be rich and abundant, and that the prescribed tonic was for the purpose of increasing the appetite.

Pardon here a little digression, for an experience which I had in younger days, when engaged as a dispensary physician, seems important enough to be related on this occasion. This experience was a great lesson to me. I have borne it in mind ever since, and I wish I could impress it upon philanthropists who create dispensaries, impress it upon physicians and charity workers alike. A young man who had been out of employment for some time, owing to a moderately advanced case of tuberculosis, came to me for advice. I examined him, took his weight, and found him in a fairly favorable condition. I advised the regular treatment and ordered an additional tonic, so as to increase his appetite. He returned to the dispensary after about ten days, when he did not look quite as well. He was again put on the scales and I found that he had lost nearly four pounds in weight. My first question was "how did the tonic act, has it not increased your appetite?" The answer was "yes, it has indeed; my appetite has been increased, but I have virtually no means to gratify it. I have lived on bread and crackers and a little milk, and I must continue to do so in order to pay my rent." When prescribing that tonic, in order to increase the appetite of the young man, it never entered my mind to also ask him whether he would be able to gratify the appetite which I hoped to increase.

A dispensary for the consumptive poor, no matter how elegantly built, how hygienically constructed, no matter how skilled the mechanical staff, nor how abundant the supply of medicine, becomes a farce if there is not attached to it a system whereby the consumptive without means can be provided with food. It there is ever an occasion for co-operation between the medical profession and organized and scientific charity it is in the perfect working of a tuberculosis dispensary. The charity organizations could investigate the cases which apply at the dispensaries and determine whether there was an abuse, or the greatest need of charity. They could be helpful in providing food, when it was evident to them that the patient had no means to do so himself, and then even the dispensary treatment might prove a success in ambulant tuberculous cases.

The importance of the work done by special tuberculosis dispensaries has been fully recognized in France and Germany, where a number of such institutions are in operation. Only very recently two ladies donated 800,000 francs to the city of Paris for a municipal dispensary for the treatment of tuberculous patients.

After this little digression, let us return to our friend, the honest laborer. His life story is soon finished. He has lingered for a little while, hopeless, helpless, until the end came. He had to die a far too early death, not because his disease was an incurable one, but for the reason that an early, timely, and constant treatment was not within his reach. Concerning this class of consumptives, I have said that your first impulse would be to remove the patient to a special hospital or sanatorium. In a paper on "The Present Aspect of the Tuberculosis Problem in the United States," which I prepared for the meeting of the American Medical Association, I give the result of careful inquiry into the provisions which the States and principal cities of this country have made for the consumptive poor. I will not burden this paper with statistics, but will simply summarize. Thus far, out of the forty-eight States and Territories which have reported to me, only one, Massachusetts, has a State sanatorium in operation, but in the following nine States, viz., Connecticut, Louisiana, Maryland, Minnesota, New Hampshire, New York, Ohio, Rhode Island and Wisconsin, the establishment of State sanatoria for the consumptive poor is under consideration, and in several States some are already in process of construction. Maryland has a State hospital for the consumptive poor; Minnesota has a hospital for tuberculous prisoners, Mississippi has a hospital for the tuberculous insane, and Texas has an agricultural colony for tuberculous prisoners. Only four cities, Cincinnati, Boston, New York, and Buffalo, have special institutions, provided by municipal funds.

New York City has, at the utmost, 1,000 beds to accommodate 10,000 absolutely poor consumptives, and 10,000 consumptives of moderate means. You will agree with me when I say that the people of few States and cities are better off than we are in New York. There is no disease in which the physician is so powerless to benefit his patient as in consumption among the poor, and there is no disease where, by proper hygiene, abundance of food and good nursing, the physician can accomplish more in the home of the well-to-do.

What good could scientific and trained charity workers and medical men accomplish had they the means at their command? And these means are nothing more nor less than a sufficient number of well-equipped special hospitals and sanatoria for the consumptive poor.

Whatever may be our work in preventing the development of tuberculosis, for the time being we must exert all our influence with the municipalities, statesmen, and philanthropists, to impress upon them the urgent necessity of a sufficient number of sanatoria in which to place immediately all cases of consumption which either constitute a source of infection to their kin and neighbors, or who cannot receive in their homes the proper treatment which their condition demands.

All those cases which we classified under numbers one and two are in such urgent need of better shelter and treatment that we must not even lose time in investigating the reasons for the evident extreme poverty. That excellent maxim of modern charity work, "help the poor to help themselves," cannot find immediate application in these cases. Widely different, however, is work when directed toward preventing tuberculosis among the poor. In New York the charity organizations have long since discovered that the families most frequently reported destitute and principally afflicted with tuberculosis were the ones living in the worst and most crowded tenement houses, under the most deplorable hygienic conditions. The New York Charities Organization, the New York Society for the Improvement of the Condition of the Poor, the United Hebrew Charities Organization, and others united to bring about the enactment of a tenement-house law which, even with its present modification, brings terror to greedy landlords, sweatshop bosses, unscrupulous contractors, and speculators. This new tenement-house law resulted in the creation of the office of a permanent tenement-house commissioner. Through the enactment of wise and restricted legislation, the erection of unsanitary tenements is no longer possible, buildings which are unfit for habitation are condemned and old tenement-houses must be improved and properly managed. Indirectly, this tenement-house reform movement stimulated the building of model tenement-houses as a commercial enterprise.

To my friends, the charity workers of the city of New York, who have brought about this tenement-house reform, I gladly concede the honor of having accomplished one of the best, most practical, and most important portions of the work in the combat of tuberculosis as a disease of the masses. It is here where we must commence our work in preventing further development of pulmonary tuberculosis, for no matter how many sanatoria and special hospitals we may have, so long as there are unsanitary, filthy, dark and dreary tenement-houses, so long will consumption prevail among their inhabitants. Without the better housing of the poor the tuberculosis problem will never be solved.

Thus, after pleading for sanitoria and special consumptive hospitals, let it be our next duty to urge upon our philanthropists to stop for a little while building libraries, colleges, and churches, and build model tenement-houses in their stead. Let them give to the laboring man an opportunity to enjoy, at a moderate price, the comfort of a cheery, healthful home. They will thus render happy many a family, and indirectly help prevent the dissemination of tuberculosis. By giving to the laborer a comfortable home at a moderate price the philanthropist does not pauperize the honest workingman, but helps to make of him a more dignified and, probably, a more sober citizen.

No one knows, perhaps, better than the visitors of the poor and workers among the unfortunate how the untidy, dreary, badly-ventilated and badly-lighted rooms in the crowded tenements, stuffy and close in summer, insufficiently heated and cheerless in winter, often drive the laborer, after a day's hard work, into the brightly lighted and seemingly cheerful and attractive liquor saloon. As is well known, alcoholism is a strong predisposing factor to tuberculosis. Another is malnutrition. Here we know that it is just as often, and perhaps more frequently, the ignorance of the housewife among the poor, who does not know the art of choosing and preparing the right kind of food, which so often causes discontent. Education in housekeeping of factory and shopgirls before they marry seems to me the only remedy to counteract this evil. I say again, give to the laboring man a clean,cheerful home, be it ever so modest, and an intelligent housewife who can prepare good and appetizing meals, and the rumshop will have less temptation for him.

And now let us see whether it is not possible without pauperizing the poor to solve the problem in connection with the third class of tuberculous patients. There exists in the German empire a law whereby every laborer and employee earning less than 800 marks per year must be insured against accident, old age, and disease (including tuberculosis). These State invalidity and insurance companies, realizing that it is to their advantage to treat the tuberculous cases as early as possible, instruct their physicians to exercise the greatest care in the detection of early tuberculosis, and when such case is discovered the patient is sent immediately to one of the existing sanatoria. Often in less than four months' treatment these cases are discharged as cured. The insurance companies, seeing the advantage of the early treatment, particularly in sanatoria, themselves created such institutions. Independent mutual benefit organizations imitated the work of the State insurance companies, and the result is that there exist now in Germany nearly one hundred sanatoria, accommodating about 9,000 patients, a small number of them for the absolutely poor, but a large majority for patients who, by right of their insurance policies, or membership in mutual benefit associations, must be considered paying patients.

How would it be if one of our most thickly populated States, after having created a number of sanatoria, would try the experiment of a State tuberculosis insurance company? How many families, even of the classes in fair circumstances, but in which tuberculosis is dreaded on account of the disease having been the cause of the death of some of their members, would not gladly avail themselves of this opportunity, especially since the existing life insurance companies refuse applicants with a family history of tuberculosis? This opportunity offered by the State would mean giving to their children the certainty of being offered the best possible chance of recovery should they be taken down with the family disease. No matter at what age, so long as the individual remains insured, there would be the State Sanatorium to receive and treat him. A payment of 50 cents a month from the birth of the child would give to the State insurance companies, after fifteen years, with the accrued interest, a capital of nearly $150. By paying the aggregate amount up to the date of application, any predisposed individual might be insured at any time, and such an institution be called into life at once.

It is well known that the greatest chance of a predisposed individual being taken sick is between the age of puberty and thirty. The chances of the disease becoming healed without ever having been discovered are at least between 20 and 25 per cent., that is to say, that out of every hundred autopsies made on people having died accidentally, or of diseases other than tuberculosis, twenty to twenty-five show evidences of healed tuberculous lesions (cicatrization or calcarious formation). The chances of this disease being cured in from six to nine months, if it is discovered at an early period, are at least 50 per cent.

It is not necessary to be an insurance expert to see that the State could hardly be a great financial loser by creating such an insurance institution. But the greatest benefit which would accrue to the State or commonwealth through such an enterprise would be the paving of the way toward a complete State or municipal control of tuberculosis among that portion of the population, which, owing to its social conditions, could otherwise not be properly cared for, and would constitute forever an impediment to the thorough prophylaxis and possible eradication of the disease.

We have thus far endeavored to answer the question "What shall we do with the Consumptive Poor?" as it relates to the absolutely poor who appeal for help, those whom we meet by chance, and the not-absolutely poor. For the ambulant cases, who are up and about, doing a little work, we have pointed out the value of special tuberculosis dispensaries, and how they should be managed in order to effect cures. There are two more classes of tuberculous patients who are of interest to the scientific charity worker. One is that large class of individuals who work, although afflicted with tuberculosis. They work in shops, factories, and stores, and they continue to work until they can work no longer, or until their disease becomes objectionable to their employers or fellow workers. Yet I believe that the lives of the vast majority of these patients could be saved if they had an opportunity to change their occupation; if they were allowed to do outdoor work instead of being compelled to live a sedentary or indoor life. If some sort of agricultural colony could be established, for patients suffering from the early stages of pulmonary tuberculosis, I am sure that many patients would not only be restored to perfect health, but that such a colony could be made self-supporting and, perhaps, prosperous. It goes, of course, without saying, that such a colony must have a physician who should not only watch over patients, but should also decide the amount and kind of work the patients should do. In Texas, where the first colony of tuberculous prisoners has been created, and where they make farming and gardening the principal occupation of the colonists, the experiment resulted in the cure and improvement of a large number of prisoners, and in an actual surplus from the earnings of the colony. I wonder whether it would not be a wise and judicious procedure to inaugurate similar colonies, for the consumptive poor of large cities, supported by either the State, municipality, or by philanthropically inclined private individuals. As to the amount of good that could thus be accomplished it is hardly necessary to say more. Such a colony might even be in connection with a sanatorium, where the earlier cases are treated.

The last class of patients which interest us are the thousands of children afflicted with some of the many forms of tuberculosis, or who are strongly predisposed to consumption. We all have seen in our wanderings through the crowded streets of the tenement districts the many pale and emaciated children, with evident scrofulous and tuberculous manifestations. It is an interesting, but significant fact that while tuberculosis in the adult is curable in many cases, in children the disease *is twice* as curable. In European seaside sanatoria from 50 to 75 per cent. of absolute cures are annually reported. Seacoast climate, good food, and bathing in the ocean, seem to be almost the specific treatment for children suffering from tuberculosis, or scrofulosis, the latter being only a milder form of the former. Is it not strange that we in this country, with our far-extending, beautiful seacoasts, have virtually no such institutions, while France alone has, according to *La Tuberculose Infantile* of December, 1901, along its seacoasts no less than twenty-four sanatoria for tuberculous and scrofulous children, offering accommodation to 3,923 patients. All these sanatoria are provided with educational facilities, so that the children's intellectual development does not suffer. To place these little invalids in such institutions would be another answer to the question what to do with the consumptive poor, and to make propaganda for such school sanatoria for tuberculous and scrofulous children must be as imperative to us as our pleas for the establishment of sanatoria for adults. The child of to-day is the man of to-morrow, and the more children we cure of this disease now the smaller number of consumptives we will have to take charge of in the future.

I will now summarize as briefly as possible: We must remove those suffering from tuberculosis in the second and more advanced stages of the disease to either special hospitals or sanitoria. We must try to get as many as possible of the incipient cases to submit themselves for treatment to special tuberculosis dispensaries, and, from the frequenters of such dispensaries, select, according to their condition, as many as can be accommodated for either the tuberculosis agricultural colony or a sanitorium for incipient cases. In the seaside school sanitoria, which should be numerous, we should place all tuberculous and scrofulous children and those strongly predisposed to consumption. Every charity organization society, which wishes to deal with the tuberculosis problem effectively, must engage a competent physician to examine not only the patient pointed out to him, but also all the other members of the family, and thus detect, as far as possible, all existing cases of tuberculosis. Many lives may thus be saved; and the physician, being at the same time a sanitarian, will give directions to the family to stop, as far as possible, the propagation of the disease.

To do such effectual work we need money, and a great deal of it, and the question now is where to get it. Even if the municipalities would be willing to help us, and a great many are, no city in this country, nor in any other, is able to cope alone with the tuberculosis problem. In Europe the royalty and the aristocracy of birth and finance have created hundreds of sanatoria, and these institutions have made their influence felt already in a marked reduction in the mortality from tuberculosis. We have no emperors, no kings, no aristocracy by birth in this country, and let us be grateful for it. We have something better. We have an array of philanthropists whose generosity has never been equalled. According to Dr. Rossiter Johnson, $107,360,000 were given by American citizens for educational, religious, and general philanthropic institutions during the single year of 1901. All previous records have been outdone by this aggregate, the highest total for any previous year having been $62,750,000. It is a good augury that the first year of the twentieth century should have distinguished itself so remarkably. Our Carnegies, our Rockefellers, Vanderbilts, Morgans, Pearsons, our Helen Goulds, Phœbe Hearsts, Jane Stanfords, (Mrs.) Emmons Blaines, have given us fortunes for universities, colleges, and libraries, and have thereby made us and our children their lasting debtors.

It is but natural that those familiar with the needs of the consumptive poor in this country should look for help in solving this difficult tuberculosis problem to the large-hearted American men and women who make such noble use of their wealth. There are now, perhaps, plenty of libraries and colleges, and even general hospitals, everywhere; but there is a penury of good model tenement-houses; there is a need for public baths, which should, at a moderate price, be at the disposal of the people winter and summer, and for some hours in the evening. There is a scarcity of decently-kept places of amusement, open all the year, where the laborer and his family may spend a pleasant Sunday afternoon and partake of non-alcoholic drinks. There is a penury of hospital and sanatorium facilities for thousands of poor consumptives who could be cured if only taken care of in time. Sanatoria for consumptive adults, as well as seaside sanatoria for scrofulous and tuberculous children, are a crying and urgent necessity for the majority of our large American cities. The more consumptives we cure, the more breadwinners we create, and the fewer will become burdens to our communities. As the conditions are now in most of our cities and towns, the majority of consumptives are doomed to a certain and lingering death; and, if they are careless or ignorant of the necessary precautions, they will infect some of their own kin and neighbors.

When you call on your philanthropic friends to help you solve this great tuberculosis problem describe to them the sufferings of mind and body of these people who must suffer and die, not because their disease is incurable but because there is no place to cure them. I am convinced that if our generous and wealthy fellow citizens could but see for themselves these conditions, instead of more new libraries, universities and colleges, we would soon have better tenements, more playgrounds and parks for children, and an abundance of sanatoria and hospitals for our consumptive poor. Thus we would come nearer to the solution of the tuberculosis problem than we have ever been before in the United States.

INTUSSUSCEPTION WITH A REPORT OF THREE ADDITIONAL OPERATIVE CASES.*

By JOHN F. ERDMANN, M.D.,

CLINICAL PROFESSOR OF SURGERY IN THE UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

In an active service of over six years in an emergency hospital, located in a densely populated district, I have seen but few cases of acute intussusception, although in my private practice I have been particularly fortunate in seeing, in consultation, what might be considered (judging from the rarity of this condition) quite a number of cases of this disease.

The earlier that we consider intussusception purely a surgical condition and so treat it, the better results we shall obtain. I base this assertion entirely upon the histories of the cases previously reported by myself and included in this paper with the additional cases reported herewith. It will readily be observed that every hour after the first twelve the dangers of gangrene, sepsis, etc., rapidly increase, and, therefore, I believe, should mechanical measures at reduction, such as posture and enemata with abdominal massage, be used without positive success during this time, that surgical interference is absolutely demanded. To make it more forcible, I would say that, given an unsuccessful attempt at reduction by means of a high enema with posture, abdominal section with a view of reduction, etc., is the only hope for recovery of the patient.

The conditions arising in the gut can be allied to those following in acutely irreducible hernia, as adhesions, engorgement with strangulation, and gangrene, and these of necessity accompanied and followed by the symptoms and signs usually seen in each of the above-mentioned conditions.

The question of operative shock in children is not worth discussing, as they bear operative interference as well, if not better, than adults, and it is an interesting picture to observe the change from shock due to intussusception to the condition of absolute quietude following operative procedure.

The question of the site of the incision is one of importance only when a tumor is not palpable. This latter condition may be due to the mass being behind either the hepatic or splenic costal arch (instances of these conditions were observed by me in several cases), or where there is so much abdominal distention as to prevent deep palpation. In these cases it is an invariable rule with me to open the abdomen through the right rectus. This conclusion has been arrived at as a result of the preponderance of cases in which the mass is found to the outer border of the right rectus, and again due to the fact that the final section of gut for reduction is, in practically every case, the ileocæcal portion or ileum near the cæcum. Those cases in which the tumor presents in the region to the outside of the left rectus can usually be manipulated through the above incision until the mass is within easy reach for exposure. Resection is demanded in those cases where reduction is impossible, due to adhesions or engorgement of a portion of the gut, and in cases of gangrene, in which the patient's physical condition will allow of a more extensive operative procedure. In a former paper I advocated making an artificial anus temporarily, but at present I am of the belief that a few minutes more of operative time devoted to resection will not exaggerate the grave aspect of these cases, but is likely to be followed by a successful result rather than by an exhaustive artificial anus or intestinal fistula, as is seen when an enterostomy is performed. In cases of poor physical condition with gangrene, enterostomy naturally is the only procedure countenanced. I feel certain that no physician or surgeon at the present date places any reliance in the former method of inflation, and, personally, I would not suggest enemata with posture in cases in which the tumor appears to be proximal to the cæcum, for in this class of cases time is lost at the expense of the physical condition, and a certain risk of rupture of the gut is accepted.

---

*Read before the Orange Mountain (N. J.) Medica Society.

The method of procedure at reduction is simple enough, and exceptionally easy in all non-adherent and non-strangulated cases. Success usually crowns one's efforts if it be remembered never to try to pull the intussusceptum out, but to reduce it by gently squeezing at the distal or colonic end.

All of the cases of trauma, *i. e.* peritoneal lacerations, etc., seen by me were due to pulling and haste in attempts at reduction. Occasionally one will meet with a case in which there is a degree of irreducibility, due either to adhesions of a few hours standing or to a circular contraction of the intussuscipiens or both. These conditions can frequently be overcome by gently introducing a blunt instrument between the intussusceptum and intussuscipiens, thereby liberating the adhesions and also overcoming this circular contraction or spasm, bearing in mind during this procedure to continue the gentle taxis from the distal or colonic end. Whether the mesentery or mesocolon shall be plicated or shortened after reduction is a question which must be dealt with according to the conditions found. Personally, I see no need for this additional feature, and have practised it in but one case, and in that ininstance I had an abscess develop, which I always attributed to the catgut used, although, fortunately, the result was a recovery.

One cannot pass the subject of operative interference without a due consideration of the possibility of ventral hernia. This has occurred in one of my cases, and in this case my incision was directly over a palpable tumor in the left lumbar region. The incision was made over the outer border of the left rectus, but owing to lack of suture material on hand, a number one formaldehyde gut was used to sew up the rectus sheath. Another causative factor of the hernia, besides the size of the catgut used, was that the patient, a seven-year-old girl was an uncontrollable one. She got out of bed during the night of the operation, in search of water, and was found sitting up in bed a number of times afterward. In this case there was a distinct ventral hernia of some size at the time of the first dressing on the seventh day, possibly due to the absorption of the No 1 catgut before union had become solid. This herniation was improved, under bandaging and strapping, to such an extent as to be hardly noticeable at the present time, about twenty-one months since the operation.

I do not believe that, given the proper suture material and a proper degree of attention by the nurse or attendants, the question of hernia should ever receive a second consideration if the incision be made through or behind either rectus, or if it be an intermuscular one and done after the manner of McBurney's interval appendix incision.

In one of my cases, case number twelve, the last of the three reported, there was a double invagination, the first occurring in the ileum, about five inches from the ileocæcal valve, while the second was of the ileocæcal variety. The first was intussuscepted in the colon also. That this condition may exist must be borne in mind, and also that more than one intussusception at remote points may exist. It is, therefore, necessary to carefully palpate the entire intestinal tract before closing the abdomen.

The ages of my patients ranged from sixteen weeks to thirty-eight years.

The duration of the intussusception in the fatal cases was from two and one-half to seven days, while in the operative recoveries the duration of the intussusception was from ten to seventy-one hours.

It will be seen that the deaths were in cases, generally speaking, of over sixty hours' duration (the one of two and one-half days was a case of gangrene with resection in a child nine years of age), while the recovery cases, all but one, a child of six months, case number twelve, were under thirty hours, four of them being under one day's duration.

Thirty per cent. of all cases of acute obstruction may be assigned to intussusception, and of these 30 per cent. fully 50 per cent. occur in children under ten years of age, and of this percentage fully one-half are found in children under the age of one year. The percentage of cases rapidly diminishes between the ages of five and fifty, and after this latter age an increase is again noted. Should an analysis of these cases be made, it will be found that after fifty the majority are due to causes within the bowel, chief among them being tumors and strictures. The varieties of intussusception that we see are in the order of frequency in which I met them: Iliocolic, where the ileum and cæcum pass up into the colon; ileocæcal, in which the ileocæcal valve forms the apex of the intussusception; ileal, or enteric variety, where the intussusception is made up entirely of small intestines; and colonic, made up entirely of colon.

My observation in the ten operative cases reported is at variance as to the frequency with the reports of former writers, as in looking up the literature with reference to this subject the enteric or ileal has heretofore been placed first. This may be due to the findings, on autopsy, of cases of enteric intussusception that are now proven to be entirely post-mortem in nature.

It would seem to the writer that all cases should be classified with reference to intensity and fatal termination into:

(1) Acute, those lasting less than seven days; (2) Sub-acute, those terminating between seven and twenty-eight days; and (3) Chronic, those terminating after a month or more.

Some of the causes producing the irregular peristalsis that is invariably necessary to the production of intussusception have been classed under the general headings of (*a*) Former conditions of health; (*b*) Pathological nature; (*c*) Anatomical causes; (*d*) Sex and nationality.

(*a*) *Former conditions of health.*—Diarrhœa may be assigned as the chief factor, as in several of my cases the history shows a preceding diarrhœa with much straining. Children of robust health, it is said, are less liable to this disease than puny children. The writer cannot agree with this latter statement, as the majority of his cases were well nourished.

(*b*) *Pathological nature.*—Tumors, polypi, etc., and Meckels diverticulum. (See case number 2.)

(*c*) *Anatomical causes.*—Include long and lax mesentery, although I am not satisfied that there was any extra length to this structure in a single case operated upon by me.

(*d*) (1) Sex, and (2) nationality. (1) In the twelve cases reported six cases are credited to males and females alike; (2) Five were of Irish or Irish-American, two were of German, and five were of Polish or Russian parentage.

The following is the order o frequency in which important diagnostic signs and symptoms occurred in the cases reported by the writer: pain, shock, vomiting, restlessness, tenesmus, passage of bloody mucus or blood, tumor, obstruction, peritonitis and sepsis. Pain was present in every case seen by the writer, the patient crying out for some time. With this condition distinct evidence of sensitiveness or pain on pressure was elicited in all cases. Shock was observed in the majority of cases; a few minutes in some cases, while in others it was present to the time of reduction or death. Vomiting was not an early symptom, *i. e.* in the first twenty-for hours, but was present in almost every case of over that duration. Diarrhœa and vomiting, it is well to remember, exist in many cases previous to the onset of intussusception, and should, therefore, not be taken as diagnostic factors. Restlessness—the majority of my cases were moving and tossing from side to side during the non-septic period; after this period the picture is one of general septic peritonitis. Tenesmus was present in every case, except those in which sepsis predominated.

Blood or bloody mucus had been present in every case seen by the writer. If a careful history were taken the fact would be established that a fair small-sized stool with blood was passed, and that this was followed by straining and the passage of apparently pure blood or bloody mucus. The fecal matter passed in these cases is not an evidence of a pervious bowel, but means that the fæces below the intussusception have been extruded. Evidence of flatus after the first blood-tinted stool is usually absent. Tumor is not a frequent evidence by rectal palpation, and certainly not always found by abdominal palpation. As before stated, the tumor may be behind the costal arch, or the abdominal distention so great as to prevent palpation of the tumor, even if in the accessible regions. When the tumor cannot be palpated either through the wall or by rectum, reliance must be placed upon the symptom complex, which usually is sufficient for diagnostic purposes.

In this disease, as in all cases where peritonitis is prone to arise, the use of opium cannot be too strongly condemned. Small doses of paregoric in case number eight masked the general condition so thoroughly as to be directly the cause of a fatal delay in operating.

SYNOPSIS OF CASES ALREADY REPORTED.*

CASE I.—Age, eight and one-half months. Sex male. Born in United States. Parents, Irish-American. Duration, four days. Condition of patient, septic. Tumor palpable, no. Water tried, unsuccessful. Operation, yes. Condition of gut, gangrenous. Variety, enteric. Reduced, no. Resection, yes, Murphy button. Result, death in twelve hours.

CASE II.—Age, nine years. Sex, male. Born in United States. Parents, German. Duration, two and a half days. Condition of patient, septic. Tumor palpable, yes. Water tried, unsuccessful. Operation, yes. Condition of gut, gangrenous, Variety, enteric. Reduced, no. Resection, yes, Murphy button. Result, died on fourth day.

CASE III.—Age, four months. Sex, female. Born in United States. Parents, Poles. Duration, seven days. Condition of patient, septic. Tumor palpable, no. Water tried, unsuccessful. Operation, yes. Condition of gut, congested and œdematous. Variety, ileocæcal. Reduced, readily. Resection, no. Death in twelve hours.

CASE IV.—Age, seventeen weeks. Sex, female. Born in United States. Parents, Poles. Duration, eighteen hours. Condition of patient, fair. Tumor palpable, no. Water tried, unsuccessful. Operation, yes. Condition of gut, congested and œdematous. Variety, ileocolic. Reduced, readily. Resection, no. Result, recovered, complicated with pneumonia.

CASE V.—Age, five months. Sex, female. Born in United States. Parents, Poles. Duration, twenty hours. Condition of patient, poorly nourished. Tumor palpable, no; felt by rectum. Water tried unsuccessful. Operation, yes. Condition of gut, congested and œdematous. Variety, ileocolic. Reduced, readily. Resection, no. Result, recovered.

CASE VI.—Age, thirty-eight years. Sex, male. Born in Poland. Parents, Poles. Duration, sixteen hours. Condition of patient, good. Tumor, palpable, yes. Water tried, successful. Operation, no. Result, recovered.

CASE VII.—Age, three and one-half months. Sex female. Born in United States. Parents, German. Duration, two days. Condition of patient, fair. Tumor palpable, no; felt by rectum. Water tried, unsuccessful. Operation, refused. Result, death on twelfth day.

CASE VIII.—Age, four months, four days. Sex, male. Born in United States. Parents, Irish-American. Duration, thirty-six hours. Condition of patient, apparently good. Tumor palpable, yes. Water tried, unsuccessful. Operation, yes. Condition of gut, congested, œdematous; two large lacerations of wall; peritonitis. Variety, ileocolic. Reduced, some difficulty. Resection, no. Result, died; small doses of paregoric; marked symptoms.

CASE IX.—Age, ten months. Sex, male. Born in United States. Parents, Poles. Duration, ten hours. Condition of patient, good. Tumor palpable, yes. Water tried, unsuccessful. Operation, yes. Condition of gut, œdematous and congested. Variety, ileocolic. Reduced, readily. Resection, no. Result, recovered.

CASE X.—Previously presented to the section on pediatrics of the New York Academy of Medicine, April 12, 1900, and commented upon under the section transactions in the *Archives of Pediatrics* of August, 1900. This case was referred to me by Dr. L. K. Neff, March 11, 1900, with the following history: Mary C., female child, aged seven years, was seized with a pain in the abdomen at about 5 o'clock in the afternoon. The pain was followed by a small amount of blood in a stool that passed a few hours afterward. There had been no illness before that could have any bearing upon the diagnosis or causation of the condition found. Her family physician, upon being called, used all the remedies usual in such cases. I saw her at 9 o'clock the following day—twenty-nine hours after the onset—at which time she presented the following signs and symptoms: anxious countenance, restlessness; pulse rapid, 116; temperature, 100.4°F.; respiration, shallow; abdomen, slightly distended; tumor visible and palpable through the abdominal wall in the left lumbar and iliac regions and a palpable tumor in the rectum. Owing to the duration of the illness and to the fact that ordinary attempts at reduction had been practised, operation was done at once. The patient was chloroformed and an incision was made through the left rectus sheath, the rectus was pushed aside, and the posterior portion of the sheath was cut through. Upon opening the peritoneal cavity a tumor, involving the descending colon, sigmoid and rectum was exposed. No general peritonitis was present. Reduction was readily accomplished, but great care

---

*In the *Annals of Surgery* for February, 1900 was necessary on account of two rents in the serosa, produced by distention, due to the rather firm packing of the gut in the sigmoid. One rent was about one-and one-half inches in length, in the long axis of the gut; the other was about one inch in the transverse diameter. These rents were sewed with fine catgut, and then the intestine was reduced by means of pressure at the distal end of the mass. It was found that the colon alone had to be dealt with, the intussusception beginning at the hepatic flexure of the transverse colon; at this point the intestine was very œdematous and ecchymotic. No attempts at shortening or plication of the mesocolon were made. In all previous cases this procedure was found unnecessary. This is the case mentioned in which a hernia followed operation.

Case XI.—April 26, 1901, while making rounds at Gouverneur Hospital, one of the dispensary staff referred this case to me. Boy, nine months old, well nourished, history of diarrhœa and cramp for several days. Pain in abdomen three days ago. Blood and mucous stool for the greater part of three days. Temperature, 100°; pulse, 138. Abdomen distended. Tumor not palpable until under ether; then found in right iliac fossa; no rectal tumor. Operation iliocæcal variety. Marked difficulty in reduction. Large laceration of serosa, which was sutured. Death in three days. Enema previously tried.

Case XII.—Case referred to me by Dr. J. F. Moore and seen with him by Dr. Emmet Holt, May 2, 1901. Child six months and four days old; female, fair state of nourishment, attack seventy-one hours' duration, condition apparently excellent. Early manifestations of pain, mucous and blood stool. Tumor not positive, even under ether. Operation—tumor apparently of iliocolic variety; later proved to be an ileocæcal intussusception containing an ileal intussusception. Position of tumor from usual site of hepatic to splenic flexures and high up under the arch. Upon reducing the iliocolic portion, which was an easy matter, it was seen that an ideal or enteric intussusception was extruded from the cæcum and colon that involved the ilium about five inches from the iliocæcal valve. This was also readily reduced. The entire operation was done through a three-inch incision. Patient in bed fifteen minutes after anæsthesia was complete. Recovery.

Summing up the salient features presented in these twelve cases, we find

1. That there were ten operative cases, of which five were of the iliocolic, one iliocæcal, two enteric, one colonic, and one multiple—iliocolic and enteric, varieties.

2. That only one case recovered by the use of injections.

3. That one death occurred in which enemata, etc., had been used. No operation allowed.

4. That of ten operative cases five died and five recovered, and of the deaths three were cases operated upon as a last resort after all mechanical means had been exhausted, two being resections for gangrene and the third septic from a seven-day duration of the intussusception.

5. That tumor could be palpated though the abdominal wall in five cases, while through the rectum only three cases were palpable.

6. That had we cases 1 and 2 to operate again, resection would not have been done, but a temporary enterostomy would have been made.

Although the mortality rate is 50 per cent. in the entire lot, it must be remembered that the cases terminating fatally were of two and one-half, three, four, and seven days' duration when operated upon, and that of these, three were practically moribund at the time of operation.

N. B.—Since writing the above the author has operated upon five more cases, all under twelve months of age.

ON THE TRANSPORTATION OF MOSQUITOS BY VESSELS.

By EDMOND SOUCHON, M.D.,
NEW ORLEANS, LA.
PRESIDENT OF THE LOUISIANA STATE BOARD OF HEALTH

We have read articles in which the presence of mosquitos on board of vessels is assumed, but in view of the absence in medical literature, as far as we are aware, of any regular publication bearing on the transportation of mosquitos by vessels, we present the following information, although it is not as complete and satisfactory as we intend to make it later on.

The fact that the presence or absence of mosquitos on board of vessels may be considered as a basis for quarantine regulations is the reason of this rather premature and immature communication.

The observations were made by the Marine Medical Inspectors which the Louisiana State Board of Health places aboard of fruit vessels coming from the fruit ports of Central America which carry passengers, or which trade with infected ports or specially dangerous ports.

As few and incomplete as these observations are, they are quite interesting and valuable since they are the only cases scientifically observed and reliable. They are as follows:

I. 1901.—Dr. D. C. Anderson, fruit steamer *Foxhall* from Bocas del Toro, United States of Columbia: "Some time ago you requested me to look for mosquitos while *en route* from Bocas del Toro. I searched diligently for them in every crook and cranny of the steamship *Foxhall*, but was unable to find any at all."

II. 1901.—Dr. R. W. O'Donnell, fruit steamer *Breakwater* from Port Limon, Costa Rica: "In compliance with your request to inspect the vessel for mosquitos, will say that each day for three days I went down in the hold of the vessel, but was unable to find any."

III. 1901.—Dr. D. S. Wilson, fruit steamer *Olympia* from Port Limon, Costa Rica: "In accordance with your request that I find if mosquitos are carried in the hold of the steamship *Olympia*, I wish to state there were none this last voyage, nor have I ever seen any there, although having been down there many times."

IV. 1901.—Dr. George J. Tusson, fruit steamer *Anselm* from Belize, British Honduras: "According to your request, I have looked for mosquitos in hold of vessel plying between here and Central America and would report that none were found on the day previous to our entering the Jetties."

V. 1901.—Dr. W. B. Robertson, fruit steamer *Hispania*, from Port Limon, Costa Rica: "Just before reaching Port Eads, I made required examinations with negative results. It may be desirable to state that a very fresh breeze was blowing for upward of forty-eight hours prior to making the bar, consequently the strong currents of air down the wind-sails would in all probability have blown the mosquitos away from any accessible parts of the hold."

VI. 1901.—Dr. T. S. Adams, fruit steamers *Condor* and *Hiram* from Bluefields, Nicaragua: "I beg to state that I went down in the hold just prior to entering Port Eads and did not find a mosquito, but as this was an exceptionally rough trip

I am inclined to think the strong winds and rough sea may have had more than usual force in clearing them up. There were three mosquitos that stayed in my state-room from New Orleans to Bluefields. I did not kill them just to ascertain how long they would stay, though the weather was good going down and the room was well ventilated."

VII. 1901.—Dr. W. G. Thigpen, fruit steamer *Alabama* from Bluefields, Nicaragua: "I find that some few mosquitos are to be found at all times, though after the first two days they are present only in the unventilated parts of the ship, *i.e.* lower hold, etc. They are only to be found by a careful search."

VIII. 1901.—Dr. G. H. Tichenor, fruit steamers *Utstein, Origen, Alabama, Olympia* from Bluefields, Nicaragua: "I have watched during the present quarantine season to ascertain whether or not mosquitos remain aboard ship during the entire voyage between this port and Port Limon, C. R., and conversely, and am of the opinion that they do *not* remain during the whole voyage. I have not discovered them later than three days after leaving port."

IX. 1901.—Dr. J. E. Heidingsfelder, fruit steamer *S. Oteri* from Belize, British Honduras: "I have examined the hold of the steamship *S. Oteri* for mosquitos, beg to advise that I have done so on two trips of the above vessels and found same free from mosquitos three days after leaving Central American ports."

X. 1901.—Dr. W. W. Samuell, fruit steamer *Venus* from Port Limon, Costa Rica: "I have observed mosquitos in cabin of steamship *Venus* in considerable number during entire passage, five and one-half days, from Port Limon, C. R., I think drain from ice-box serves as breeding place."

In résumé six medical inpectors report they found no mosquitos aboard, but two of these state that the rough weather was likely the cause that none were found.

Four medical inspectors report that they found mosquitos aboard, one of them throughout the whole voyage from Limon, five and one-half days."

It is noteworthy that at Port Limon the vessels are at least 300 yards from the shore and that mosquitos were seen on one of the vessels, the *Venus*.

The marine medical inspectors of the Louisiana State Board of Health, placed this year on board of the Morgan steamers which anchor away from shore in Havana Bay, reported verbally to the president that mosquitos have been seen on board while at anchor.

As stated above, we recognize that these observations are too few and too incomplete to be accepted as definitive, and readers will kindly bear in mind that this paper is to be regarded merely as a preliminary note.

The subject has been taken up again this year in a more elaborate and systematic manner. The medical inspectors are instructed to report on each trip whether they saw mosquitos at the wharf, at the fruit ports, in what number, the time of the day they were first seen, how long they remained visible, and direction and force of the wind. The same observations are to be made when the vessel is at anchor away from the shore, without having come to the wharf at any time. The inspectors are to visit all parts of the vessel as soon as she starts from the fruit ports and note the foregoing points: also, when the vessel has been at sea for one day, two days, three days, four days, five days, six days.

They are instructed to make the last inspection before the vessel arrives at the Mississippi River Quarantine Station, where mosquitos always invade the ships.

At the end of the quarantine season there will be about 125 reports on file, and from them it will be possible to definitely settle the question of the absence or presence of mosquitos on board and of the time they remain aboard, all points of great interest from a quarantine regulation view point.

The two following instances are the only ones we could find. They are reported in the Public Health Reports of August 9, 1901, page 1792:

MOSQUITOS BLOWN ABOARD SHIP TEN MILES FROM LAND.

Gulf Quarantine Station, August 2, 1901.

Sir: Referring to the question of mosquitos as a means of infection in disease, I have to report that the captain of the ship *America*, arriving in quarantine July 24, stated that mosquitos came aboard the vessel on the previous night, at a distance of at least ten miles from land, the nearest point being Chandeleur Island.

The opinion prevails in this locality that mosquitos are blown by southwest winds from the Louisiana marshes to this island, a distance of from ten to twenty miles, and the experience of this summer seems to accord with the opinion.

Mosquitos were few in number until about the middle of July, when, after several days of southwest winds, the number was vastly increased. At that time there was no other local condition to explain the sudden increase.

Respectfully,

(Signed.) P. C. Kalloch,
Surgeon, U. S. M. H. S.

NUMEROUS MOSQUITOS AND COCKROACHES ON SPANISH BARK MARIA BLANQUER.

South Atlantic Quarantine Station, August 2, 1901.

Sir: I have the honor to inform you that numerous mosquitos were collected on board the Spanish bark *Maria Blanquer*, remanded from Brunswick to this station. The vessel is from Rio de Janeiro, with no sickness or history of sickness *en route*.

The vessel is interesting in that there was a perfect plague of the insects as well as Blatta Orientalis (cockroaches), on board, the personnel having to cover themselves to have rest.

When the forecastle was opened, after fumigation, mosquitoes could be scooped up by the hand.

The master is positive that there were none on board until the twenty-second day out, when some were noticed in the water-tank when opened.

The water all came from Rio de Janeiro.

Respectfully,

(Signed) Hugh S. Cummings,
Past Assistant Surgeon, U. S. M. H. S.

The writer's personal experience bears out the statement of Dr. Kalloch regarding the blowing of mosquitos from quite remarkable distances.

All those who have stayed at Bay St. Louis, on the Mississippi Sound, know that when the wind blows from a certain direction it brings with it swarms of mosquitos.

The Intercommunicability of Human and Bovine Tuberculosis.—Mazyck P. Ravenel concludes a long and detailed study of the subject by saying that the evidence at hand forces us to the belief that human and bovine tuberculosis are but slightly different manifestations of one and the same disease, and that they are intercommunicable. Bovine tuberculosis is, therefore, a menace to human health. We are not in a position at present to define positively the extent of this danger, but that it really exists cannot be denied. In the past there has probably been a tendency to exaggeration, but however great this may have been, it does not now justify any attempt at belittling the risk, and it is folly to blind ourselves to it. The eradication of bovine tuberculosis is amply justifiable from a purely economical standpoint; viewed in its bearing on human health it becomes a public duty.—*University of Pennsylvania Medical Bulletin.*

CONTAGIOUS OPHTHALMIA IN INDUSTRIAL, RESIDENTIAL AND PUBLIC SCHOOLS, AND IN ASYLUMS AND HOSPITALS.

By RICHARD H. DERBY, M.D.,
NEW YORK.

In 1886 the New York Academy of Medicine appointed a committee to study and report on the subject of contagious eye disease in the asylums and residential schools of this city. This committee invited prominent ophthalmic surgeons to conduct this investigation, and they, acting in full coöperation with the Board of Health, made an exhaustive study of the subject. These surgeons, whose names were well known to the profession of the State and the country, accompanied by inspectors of the health department, visited the fifty and more asylums of New York city. Drs. Agnew, Noyes, Loring, Roosa, Bull, Gruening, Pomeroy, Pooley, Callan, Andrews, Webster, Mittendorf, Emerson, Oppenheimer, Barker, Moore, Dennett, Isham, Lewis, Huntington, Hepburn, Carey, Bowles, and Ring made careful investigation of the condition of the dependent children cared for in the asylums of New York city, and their report was printed. Of these children they found that one out of every four had contagious eye disease. While there were asylums where but few cases existed, there were others in which more than half of the inmates had eye disease of a severe and dangerous type, and where, as Dr. Roosa reported in the case of St. Joseph's asylum, "It is a marvel to me that there is a healthy eye in the establishment."

After an analysis of these various reports, it was found that in many of these asylums, the eyes of the children were not examined before admission and that those who were known to have sore eyes were not quarantined. In a common dormitory, lavatory and living room children were found with pronounced opthalmia, in daily contact with those whose eyes were as yet unaffected.

Dr. Loring reported that in one asylum the children were all washed in one lavatory, where a group of eighteen were provided with two or three towels per day. Grave defects in plumbing were found. In St. Patrick's Orphan Asylum, the female branch, Dr. Agnew found 203 cases of communicable eye disease among 409 children examined; of these, two had one and twenty-two both eyes seriously injured. In the male branch of the same institution, among 357 inmates, Dr. Noyes reported but 105 children with healthy eyes. In the Ladies' Deborah Nursery Dr. Loring found, among 223 children, fifty suffering from contagious ophthalmia.

In St. Joseph's Asylum Dr. Roosa examined the eyes of 521 children. He reported that contagious ophthalmia existed in all classes of this asylum, that its most severe form was among the younger children, that no adequate quarantine was maintained, that eight children had one eye seriously injured.

At the St. Joseph's Industrial Home, Dr. Gruening reported 137 cases of chronic conjunctival blenorrhæa among 605 girls, making a percentage of 22.6 per cent. Here were three children with one eye seriously injured, one with both.

In the Mission of the Immaculate Virgin, Dr. Pooley examined 372 boys, of whom 127 were found with one or both eyes affected, making 34 per cent.

In the Catholic Protectory, of 2,137 children, Dr. Mittendorf found 871 afflicted with the disease—more than 40 per cent. of the entire inmates. Dr. Mittendorf wrote that "the cases were more frequent among the older children, and the longer a child remains the more liable it is to have the disease. There was great carelessness in admitting children and then neglect in treating them. No isolation whatever was practiced."

The committee appointed by this academy received reports from fifty-one institutions, containing 12,684 inmates; of these 3,862 were declared to have contagious ophthalmia. To meet the exigencies of the case the committee was satisfied that legislation was needed, and to that end "an Act for the better preservation of the health of children in institutions" was drawn up.

This act provided that each institution caring for children should have attached thereto a regular physician, whose duty it was to examine each child applying for admission. It declared that no child suffering from any contagious or infectious disease should be allowed to enter or remain in any institution in contact with children not so affected, but should be immediately isolated or placed in a proper room or infirmary, provided for that purpose. It provided against the overcrowding of dormitories. It made it incumbent upon the physician of each institution to render to the local Board of Health a monthly report, declaring therein all cases of contagious disease whatever that existed among the children under his charge.

This act was passed by the Legislature on June 14, 1886, and became chapter 633 of the laws of that year. The passage of this act was made possible by the wise counsel and earnest effort of Elbridge T. Gerry of the Society for Prevention of Cruelty to Children, and the late James Gallatin of the New York Association for Improving the Condition of the Poor.

With the passage of the act, the committee, appointed by the Academy of Medicine, was discharged and now, after fifteen years of operation of the law, it is in every way proper that a brief account should be rendered of the efficiency of the remedial measures which it embodied. The monthly reports of all the asylums and residential schools of New York city are on file at the Health Department, and these contain a statement of the physical condition of the children, the existence of any contagious or infectious disease, particularly of the eyes or skin.

Dr. Moreau Morris, the efficient medical inspector of the Board of Health, and who has, perhaps, more than any other official had to do with the enforcement of the law, has prepared a table, showing the relative frequency in these asylums of contagious ophthalmia in 1886 and 1902.

From these figures a few comparisons are instructive:

In 1886 the New York Juvenile Asylum showed 17.7 per cent. of ophthalmia; in 1902, 2.5 per cent.

In 1886 the Five Points House of Industry showed 66.5 per cent. of ophthalmia; in 1902, 4.4 per cent.

In 1886 the House of Our Lady of the Rosary showed 18.3 per cent. of ophthalmia; in 1902, 1.6 per cent.

In 1886 the House of Refuge showed 16.2 per cent. of ophthalmia; in 1902, 7 per cent.

The diminution in the number of these cases is most remarkable, and it is not extravagant to say that the benefit accomplished by this law is one of the most important contributions ever made to the well-being of society. While the statistics of all the institutions are at hand, it will be, perhaps, instructive to consider the two following reports more in detail, for here we shall see in what way a great reform has been quietly accomplished.

The graphic description of the Protectory and St. Joseph's Asylum, as given by Drs. Mittendorf and Roosa in 1886, has already been referred to in this paper.

I have had an opportunity to inspect both of these institutions in the last few weeks, and the following reports by Dr. C. Cole Bradley, to whose unselfish and unceasing labor this great improvement is largely due, I can completely verify:

It will be remembered that in 1886 the inmates of the protectory showed 40 per cent. of ophthalmia. Now, of 2,484 inmates, there are 93 cases, and of these only 48 can be classed as actively contagious ophthalmia. The percentage of the contagious cases therefore would be 3.7 per cent. These are reported monthly to the Board of Health, as required by law. The children on admission are examined and immediately isolated as they exhibit contagious eye disease. A building has been constructed for the purpose of isolation, which is equipped with school-room, work-room, sleeping-room, shower baths, etc. This isolation is absolute until the cases are cured. Then they are sent to the main buildings, where they wash apart from the others, and are inspected tri-weekly for fear of a relapse, in which event they are returned to the eye pavilion.

Each child in the institution has its individual towel, and its own jet of water—no basins or bath tubs being used in the institution. The linen and towels of the contagious pavilion are disinfected and washed separately. Each month the eye-lids of each inmate are everted and examined as required by law. Each day a visit is made and treatment given.

In the male department 14.4 per cent. of the newly-admitted children showed trachoma, and it is noticeable that in 1900 this percentage was 18.5. It is regrettable that an institution cannot be totally purged of contagious eye diseases. This could only be done by preventing the influx, which prevention would necessitate the establishment of a correctional institution, maintained solely for the treatment of such diseases.

In St. Joseph's Asylum in 1886 Dr. Roosa found 58.34 per cent. of trachoma. On May 25, 1902, there were here 798 inmates, and among them four cases of trachoma; six children had conjunctivitis on the border line of contagium, and reckoning these there were ten contagious cases, making a percentage of 1.2 per cent. In this asylum each child is examined on application for admission, and that admission is refused if the child shows active contagious eye disease. There are no severe cases among the younger children as formerly, the trachoma occurring in children over twelve years of age. All contagious cases are quarantined. The lids of each child in the institution are everted at the monthly examination, required by law. Each child has its own towel, and this, as well as each article of clothing, bears the child's institution number. No bathtubs or basins are used at all, and for them the shower and jet of water are substituted.

Much as has been accomplished in limiting the disease in these asylums much remains to be done. We have seen that there present themselves at these institutions children suffering from contagious eye disease. From such statistics as are at hand, it would appear that at least 19 per cent. of all these candidates have trachoma. The severer of these cases are either sent back to their homes, or, in the case of children, committed by the courts, are taken, placed in quarantine, and there treated until they are considered safe to mingle with those whose eyes are well. The striking fact remains that nearly all these children attend the public schools of New York city. Of the actual percentage of trachoma at these schools we have a fairly definite idea from these two inspections, which were ordered by the Board of Health in the last few days.

A competent ophthalmic surgeon, attended by a health inspector, makes the following report:

The eyes of the children of public schools, No. 1 (in Henry street) and No. 75 (at 25 Norfolk street) were examined.

In school No. 1, Principal Dr. Ettinger, the lids of 1,045 boys were everted and 201 cases of communicable eye disease found—19.2 per cent.

Of these 201 cases 130 were of pure trachoma and seventy-one of incipient trachoma and conjunctivitis—sixty-six of the trachoma cases were of the most severe type, with upper and lower culdesacs filled frequently to the degree of palpably narrowing the palpebral fissure, and calling, in my opinion, for almost immediate operation.

In school No. 75, Principal Mr. Boyle, the lids of 736 boys were everted, and 114 cases of communicable eye disease found—15.5 per cent.

Of these 114 cases eighty-seven were of pure trachoma, and twenty-seven of incipient trachoma and conjunctivitis. Sixty of these trachoma cases were of the most severe type, as mentioned in report of school No. 1. In making the examination only cases considered communicable were recorded. In school No. 1, which is equipped with shower baths, the number of cases was noticeably less in the classes where such baths were frequently used. The practice of having the children bring their own towels (frequently old rags) appeared to me decidedly dangerous, considering the homes of these children and the great amount of contagious disease, other than that of the eyes, in that section of the city. In school No. 75 the system of double and quadruple desks is to be deprecated, on account of the proximity of the children and their tendency to use pens, pencils and rules in common. It appears that in neither school is an examination of the eyelids of the children made. Any child showing an active and *apparent* inflammation (with redness and secretion) to the *teacher* would be sent to the medical inspector, who might send it home if, in his opinion it was contagious; the discovery of the case, however, rested with the teacher; no notice whatever being taken of the slow insidious trachoma cases.

In both schools cases were found which I recommended to be immediately excluded until the visit of the regular inspector, as the presence of such cases for a few hours would be sufficient to infect many others, if not to start an acute epidemic.

It is impossible to read these statements of the condition of the eyes of children attending our schools without acknowledging the fact that a great evil calls urgently for prompt and systematic action for its relief. Fortunately, a beginning has been made. The present department of health has already instituted a partial inspection. They will, undoubtedly, see that the work does not stop here. They will see that no less precaution for the safety of these children shall be taken where ophthalmia is found to exist than is now observed when a case of scarlet fever is recognized.

If we are to exercise an adequate control of this disease, a rigid and universal inspection of all the pupils of the schools of this city must be undertaken. This inspection must not be based upon the statement of the teacher that this child or that has sore eyes, but in each and every case by competent men the eye-lids must be everted and the condition of the conjunctival sac inspected. Then and then only can a diagnosis be made. In the vast majority of cases, and often in the most dangerous, the external appearance of the eye shows nothing. It is in the culdesac of the lid that the blennorrhoic process goes on silently, destructively undermining the health of the organ, until the catarrhal period, when the swollen lids, profuse purulent secretion, chemosis, corneal ulceration, make evident to all the acute ophthalmia that often defies all medical treatment. As well might the medical man undertake to assume the non-existence of diphtheria in a patient whose throat he has never examined as to deny the presence of trachoma among children whose eyelids he has never everted.

In view of what we have already found among the children of our schools and that contingent, who by reason of the conditions of their eyes must be refused admission to our asylums, the fact forces itself upon us that we have nowhere in this city a hospital adequate for the reception and care of these cases. Fifteen years ago, in a paper on this subject, the writer advocated the erection of such a building. The success that has attended the efforts of the physicians attached to our asylums in reducing the percentage of trachoma among their inmates, confirms him now in the wisdom of that suggestion.

In conclusion, we have the high authority of the Superintendent of the New York Institution for the Blind for the statement that the number of children in that institution at the close of the school year of 1898 was 169—a reduction since the end of the school year of 1886 of forty-seven pupils. This decrease, Mr. Wait says, for the last thirteen years is really more considerable than it appears when we take into consideration the growth of the city population within the period covered by these figures. If reckoned as percentages, the decrease would fitly emphasize the great gain in this matter of blindness, which has been the result of better sanitary and medical supervision.

Here, in New York city, we have a dense population, where we might expect to find the proportion of eye troubles much greater than in the country districts, but, thanks to better sanitation and to the timely aid furnished by our numerous dispensaries the city figures are vastly more favorable than those of the rural districts. A careful study of the figures of the last Federal census shows that in the counties of New York and Kings the number of blind persons is one to every 2,500 of population, while in the five rural counties of Allegany, Clinton, Oswego, Madison, and Schuyler there is one blind person for each 650 of population. This is a very striking comparison, and shows how great an improvement we may expect in the future.

Improved sanitation and timely medical examinations are certain to weed out a vast number of cases of incipient blindness.

In this field, as in so many others, modern science and resourcefulness are showing themselves able to overbear what seem at first sight like irremediable ills.

SUBGLOTTIC SARCOMA REMOVED ENDOLARYNGEALLY WITH GALVANOCAUTERY SNARE.*

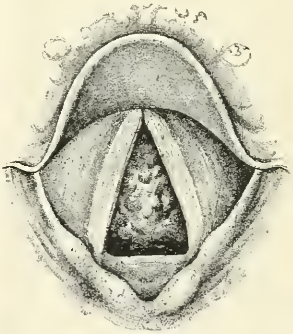
By J. W. GLEITSMANN, M D.,
NEW YORK.

SUBGLOTTIC and tracheal sarcomata are not of rare occurrence, and Bergeat[1] has compiled a complete list of published cases of sarcoma of the larynx and trachea, which was later supplemented by v. Bruns[2] in Heymann's handbook. When I therefore venture to relate to you the history of such a case, it is not for the purpose of putting another one on record, but for the two-fold reason of its successful removal per vias naturales, and of its non-recurrence thus far, after its removal five months ago; a result which, if permanent, may be added to the very few cases successfully operated in a similar manner. The family history of the patient is negative. He is fifty-two years of age, and in spite of his loss of weight is of healthy appearance, which is accounted for by his occupation as watchman at the door of a large factory, necessitating him to be constantly in the open air. Thirty-one years ago he had pneumonia, he had no gonorrhœa, no syphilis, drinks moderately, but is a heavy smoker.

I was asked to see the patient December 16, 1901, at the German Hospital, to which he had been admitted a few days before. I learned from him that his present illness began four months previously with hoarseness, which came on rather suddenly one morning upon awakening. He also suffered during two months from a severe dry laryngeal cough with occasionally a little bloody expectoration. He suffered no pain, had no dysphagia, and only recently experienced some dyspnœa when walking fast or climbing stairs.

Having lost twenty-five pounds during his sickness his strength was below par, although his appetite and other functions were normal. His voice could not be raised above a whisper.

It being evident that the source of the ailment was situated in the air passages, the attention naturally centered in the laryngoscopic examination. Fortunately, the patient did not present any local difficulties for inspection; on the contrary, he was extremely docile and not at all irritable at the introduction of the mirror. The larynx proved to be free from any anomaly except a very slight congestion of the vocal cords, both of which had normal movements and approached each other in the median line sufficiently to produce a sound, but which was not forthcoming. This seeming incongruity was at once explained by the existence of a growth below the cords, which, by its contact with the lower surface of the cords, interfered with their vibrations, necessary to voice production. The tumor, of which a drawing *in situ* is shown, filled the larger part of the tracheal space, leaving only a small opening posteriorly for respiration. The small aperture, without any undue dyspnœa, except on exertion, shows again how well the system adapts itself to slowly invading disturbances, when, on the other hand, a similar suddenly arising obstruction might have caused immediate death.



The size of the tumor could not be definitely determined by inspection, but it seemed to be as large as a small walnut, and it had to be assumed that its lower portion extended considerably downward. Its surface was uneven, and the probe met with some resistance, showing density and compactness of the tumor. From the free aperture posteriorly it was evident that the point of fixation of the tumor was anteriorly and at the beginning of the trachea.

---

*Paper read at the meeting of the American Laryngological Association, May 28, 1902.

Although no enlargement of lymphatic glands of the neck could be detected, malignancy of the growth was most probable and the proper means of its removal had to be considered.

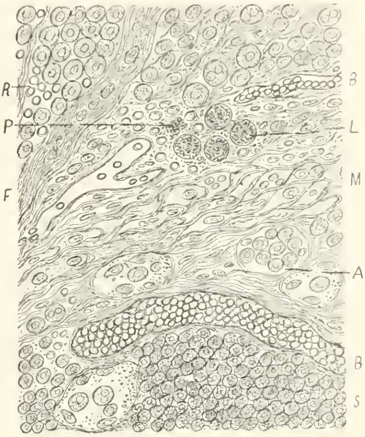
Although the difficulties of its extirpation per vias naturales with a reasonable degree of assurance of a complete removal to prevent recurrence was apparent, it was decided, after consultation with the surgeon of the hospital, to make such an attempt, to which decision I was also led by the natural desire to see what could be accomplished by laryngological measures. For such a proceeding four points had to be taken into consideration: (1) The possibility of lateral adhesions, which would make an encircling of the tumor by the snare an impossibility, but the absence of which was proven at a thorough cocainization and exploration to this effect; (2) The question if the apparent density of the tumor extended throughout its whole mass, and the accident of a fragile portion becoming separated and falling down into the trachea; (3) Although the tumor did not seem very vascular, the possibility of a hemorrhage could not be excluded; (4) The technical difficulties consisted in the ability of introducing a sufficiently wide loop through the glottis and carrying it deep enough to slip over the lower surface of the growth. Further, great care had to be exercised, to be sure that after the tumor was successfully grasped and detached by the tightening snare it could be brought upward through the glottis intact and without slipping from the snare when drawn through a passage presumably smaller than the tumor itself. It is unnecessary to mention here that all preparations for a tracheotomy were made before the laryngeal operation was begun.

Fortunately, none of the above eventualities took place, and the operation was beyond all expectation—simple, easy and a complete success. December 19, several applications of cocaine and a few of adrenalin were made to the patient's larynx and trachea, and the length of the shank necessary to reach the tumor and the size and shape of the cautery loop determined. Schech's handle and canula were employed and the iridoplatinum wire devised by me 1894[3], which is almost as elastic as steel wire, used to be carried around and under the growth. The tightening of the wire was done very slowly to avoid hemorrhage and also to be sure not to loose the growth from the loop by burning through too quickly. The removal was effected at the first introduction of the wire snare and the tumor brought through the glottis without difficulty. The basis was cauterized immediately afterward energetically with a flat burner. The two instruments used show you better than any description the depth of the seat of the tumor, the vertical bend to the lower end of the loop being 4¾ inches. No ill sequelæ followed the operation, the patient's voice began to improve the next day, and two days afterward he asked for his discharge from the hospital to celebrate his wife's birthday.

The tumor which I now show you, as also a microscopical drawing, was carefully examined by Dr. Heitzmann, whose report I herewith submit to you:

"The tumor in its different portions presents somewhat different aspects, being partly pure round-celled sarcoma, both small and large, partly myxosarcoma, and partly showing even a commencing alveolar structure. In a number of places the structure closely resembles the so-called adenoid or lymph tissue; here numerous small, round, coarsely granular, nucleated corpuscles are either closely packed together or a delicate fibrous reticulum holds varying numbers of these corpuscles. In other places the corpuscles are large and less abundant, containing either one or more nuclei; at times even nucleoli. Many of these contain a varying amount of pigment, and pigment clusters are also found irregularly scattered throughout this portion of the tumor.

"A few comparatively small and not fully formed alveoli, surrounded by a scanty fibrous connective tissue and containing variously sized granular corpuscles and developing pigment, are also found. Other portions of the tumor consist of partly fibrous and partly myxomatous connective tissue, the meshes of which contain corpuscles in different stages of development. Blood vessels, both of large and small size, are scattered throughout the specimens, and red blood globules are irregularly scattered throughout many parts of the tumor, showing a blood extravasation."



ROUND-CELLED AND MYXO-SARCOMA MAGN 300 DIAM.

BB—Blood vessels
S—Group of small round cells.
L—Large round cells, partly pigmented.
M—Myxomatous connective tissue with variously-sized corpuscles.
A—Alveolar structure.
R—Red blood globules.
P—Pigment cluster.
F—Fibrous connective tissue.

The subsequent history of the patient presents no especially interesting features. A small remaining stump was removed January 11, 1902, and the basis cauterized in the same manner. The fear that by the two operations of tightening the heated snare so near to the lower surface of the cords they might become singed with subsequent sloughing or adhesion, was fortunately unnecessary, and the voice became as strong as before with a light shade of huskiness. In this condition the patient was seen by members of the laryngological section of the New York Academy this spring.

The patient was examined under sunlight in the presence of a laryngologist on May 4, and the last time on May 18, and no anomaly could be detected.

If permitted, I hope to be able to make a short report to you about the condition of the patient one year hence.

New York, July 5, 1902.

SURGERY AND PULMONARY TUBERCULOSIS.

THE possibility of accomplishing good by surgery in cases of pulmonary tuberculosis has always been attractive, and several different methods have been suggested by which the tuberculous process might be limited or eradicated. A recently-suggested plan involves the injection of nitrogen into the pleural cavity of the side chosen first for treatment in case both lungs are involved, so that the lung may be thus collapsed and, to a certain extent, compressed by its own resiliency. This compression causes a diminution in the size of any cavities which may be present, and decreases to a large extent the blood supply and, consequently, the physiological activity of the part. All this is supposed to have a favorable influence upon the pathological processes with which we are dealing. An observer, Lemke of Chicago, has recently given the results of his experiences in *American Journal of Surgery and Gynecology*, January, 1902, and at first sight these seem to be extremely encouraging, but it must be remembered that mere mechanical pressure on the diseased lung cannot have a truly specific action on the tuberculous process. The technique for the introduction of nitrogen or even ordinary air into the pleural cavity is very simple, and does not need comment, but the necessity for sterility may be emphasized.

The results reported from this sort of treatment have in many instances been remarkable, though even in the best we cannot yet draw unequivocally favorable conclusions. It has been reported that fever has diminished, that expectoration has become less after a few days, and that with the amelioration in these symptoms, there has been a gain in weight. The reasons for these occurrences are clear enough and depend almost entirely on the decrease in the size of the area of disease from the collapse of the lung, and upon the fact that that organ is placed in a condition of physiological rest by the operation. A condition of rest is of great value and importance in any inflammatory condition, and the analogy of the success of our treatment in many cases of tuberculous joints is distinct in treating pulmonary tuberculosis by this method. Lemke makes what he considers a classification of points which are indications for attempting this sort of treatment, and many of these will suggest themselves to the reader at once. It is claimed that in some cases characterized by the acuteness of the symptoms, the effect of lung compression has been very marked, and this is also true of some other cases in which hemorrhage occur rather frequently, though the rest of the symptoms and the physical science may not be so severe. We can justly attribute the favorable effect of the procedure in such cases to the diminished blood and lymph circulation and to the lowered physiological activity in the lung.

In some other cases in which the presence of cavities of not too long standing can be diagnosticated, we may reasonably hope that lung compression would be of considerable assistance in closing such cavities, and thus reducing the suppurating area, the presence of which is an important drain upon the patient's vitality, and a serious retardation to his progress toward recovery.

It is possible that intrapleural gaseous injection may have a small field of usefulness in the treatment of persistent or profuse pulmonary hemorrhage from tuberculosis or other cause, and it would seem to be in such conditions a powerful adjunct to other resources, though not one which should be employed without grave consideration. There is some danger that compression of a tuberculous lung might, to a certain extent, cause a dissemination of the disease, for it is euident that when a tuberculous cavity is compressed, while most of its contents and most of the pathogenic material in the vessels of its walls tend to be driven outward, it is possible for a certain amount to remain in these vessels, to be forced deeper into the tissues at first and to be drawn in later by suction as the lung expands when the gas is gradually absorbed. Such a condition would not occur in most cases, but it must be thought of as a possibility, especially with cavities which have not existed very long, the walls of which are more or less soft, and do not afford the protection which the fibrous barrier of an older cavity offers. It is too soon to assign a definite value to this mode of treatment, but there is undoubtedly room for experiment and observation, so that other investigators may, if possible, bear out those whose results have been given. The foundation of any possible future success will certainly depend upon a careful selection of cases, and it must be remembered that there can be no success without the employment, in addition to the operative treatment, of all the well-recognized tonic and roborant means at our disposal, for increasing the general health of the patient.

THE RADICAL CURE OF BUNIONS.

MR. A. H. TUBBY, M. S. Surgeon to the Westminster and National Orthopedic Hospitals, writes, in the *London Hospital*, May 17, on this common and troublesome deformity of the foot.

Of the large number of persons who are afflicted with bunions, there are few, if any, who have derived permanent benefit from the various modes of treatment extolled as curative. Perhaps in slight cases the displacement and enlargement may be relieved by wearing well-fitting shoes and by other simple remedies, but the effectual treatment of more severe cases is a matter of great difficulty, largely owing to the fact of not only the soft parts being involved, but also the bony structures.

Mr. Tubby says that the term "bunion," although usually limited to the swelling formed by the subcutaneous tissues and false bursa, should be extended to include the hypertrophied head of the first metatarsal bone and the overgrown base of the first phalanx.

The commencement of a bunion is in a slight dislocation outward of the base of the first phalanx, leaving the inner part of the head of the first metatarsal bone bare, and on the latter prominence a bursa forms. As the dislocation proceeds the extensor proprius pollicis tendon is displaced outward until it forms the base of a triangle, the two remaining sides of which are composed of the first phalanx and the first metatarsal bone. When the displacement is well marked, hypertrophy of the inner side of the first metatarsal bone takes place, and oftentimes a distinct exostosis appears.

Mr. Tubby opines that palliative measures in dealing with bunions are of little avail, the enlargement of the head of the metatarsal bone continues, and some more radical method must be attempted. The only means whereby to effect a cure is an attack on the bone itself. Some surgeons have tried the plan of chiseling off the internal prominence, but this is ineffectual, because the enlargement also affects the other aspects of the head of the metatarsal bone, while excision of the false bursa is, of course, useless, since it only forms again. Other surgeons have tried removal of a wedge-shaped piece from the neck of the first metatarsal bone, but this method fails. There is, according to Mr. Tubby, only one method of radical cure in these cases, and that is excision of the first metatarsal bone. The technique of the operation is as follows:

An incision of about two to three inches long is made on the inner side of the great toe with its center opposite the most prominent part of the head of the metatarsal bone. The incision may be straight or curved, or be made so as to include the piece of skin covering the false bursa removed. If it be inflamed great care must be taken not to allow its contents to escape and be distributed in the deeper tissues. The soft parts on either side of the incision are then reflected well outward until the outer side of the bone is reached, due regard being had to the integrity of the extensor proprius pollicis tendon. This it is not necessary to divide. The joint is then freely opened, the ligaments being completely divided. With a small saw the neck of the first metatarsal bone is divided just behind the articular cartilage. The direction of the division of the bone is of importance It should be oblique from above downward and before backward. The head of the bone can now be removed with a few touches of the knife. The sharp edges of the neck of the first metatarsal bone are then trimmed off with a small pair of bone forceps, especially underneath and on the outer side. Underneath so that the edge shall not worry seasamoid bones, and on the outer side so that there shall be no sharp pressure on the branch of the internal plantar nerve. All hemorrhage having been arrested, the wound is closed. A pad is placed between the first and second toes, so as to ensure that, when healing takes place, the first toe shall be in a right line. In most cases it is better to place between the great toe a small malleable iron splint, curved in such a way that the great toe shall point sightly upward. After a week to ten days the stitches are removed and passive movements begun, and generally in two to three weeks the patient is able to get about.

It is stated that the final result of this operation is shown to be fully justified. The foot is of almost normal appearance, the great toe slightly shorter than the second, but in a straight line, and has free movement. The operation is declared to be without risk.

Bunions are looked upon as among the lesser evils to which flesh is heir, but at the same time there are few deformities which are more troublesome and more painful. An operation therefore which will effect a permanent cure—although at first thought, a more serious measure than the circumstances warrant—will, upon further consideration, be regarded as the wisest course to be taken.

TUBERCULOSIS AMONG CATTLE, FROM A COMMERCIAL STANDPOINT.

Dr. J. G. Adami of McGill University, Montreal, in his paper upon tuberculosis among cattle read at the American Congress on Tuberculosis, recently held in New York City, dwelt chiefly on the menace of the disease in relation to the livestock industry. This view of the situation is the most important, for the reason that the danger of transmitting tuberculosis from cattle to the human race is generally acknowledged to be slight, and also because anything that appeals to the pocket is a forcible cause for investigation.

Dr. Adami says squarely that the existence of tuberculosis among the live stock is a menace to that industry in this country, not only on account of the fact that the herds in America are already very extensively affected, but also owing to the tendency of the disease to spread.

In the Eastern States its ravages are already serious enough, much more so than in the West, where the existence is in the open air, and in consequence the cattle are less susceptible to the disease.

Nevertheless, Dr. Adami thinks that bovine tuberculosis is spreading westward, and points out that what we have to recognize is, that once tuberculosis gains a hold in any country it spreads with appalling rapidity.

The history of the dissemination of the malady in Denmark, Germany and Australia is a conclusive demonstration of this fact. The reason for the alarming spread of tuberculosis among cattle during the past seventy years is due to the greater development of the cattle industry, and especially to the ease of transportation.

Contrary, to the general opinion, agriculture is still far and away the greatest industry of the United States. Only two-fifths of the population of the country live in towns of 25,000 inhabitants, or more, three-fifths gain their living from the soil. If then, only 1 per cent. of the animals slaughtered were found to be the victims of advanced tuberculosis, the loss would be enormous, and Dr. Adami declares that unless the progress of the disease be arrested we must be prepared to encounter such loss.

The time to act is now, before the disease gets "out of hand."

The eradication of tuberculosis from a herd, or from a district, need not be, according to Dr. Adami, a costly matter, either for the individual or for the community. The employment of Bang's method of isolation of reacting animals will render a herd wholly free from the disease in the course of from three to five years.

Effective legislation is needed to bring about the general use of this remedy. There is a prejudice in the minds of farmers and breeders against the enforcement of any methods whereby their immediate profits would be curtailed, but a present comparatively small loss is preferable to a future large one, and if owners of herds cannot be made to appreciate the force of this argument, the alternative must be that government steps in and initiates legislation to this effect. The matter is of national significance, and should be taken in hand at once, so that a great calamity may be averted.

Dust and Disease.

There has arisen within the past few years a distinct impression, with some reaching to a certainty, that dust is a potent factor in disseminating certain diseases. It assuredly goes without saying that phthisis is greatly aggravated, if not in some instances actually initiated, by the irritating effect of dust upon the respiratory organs. Dust as a means of infection we will not discuss.

That an individual suffering from pulmonary tubercolosis in its early stages, or even a person with a predisposition to that disease, should be compelled to live in an atmosphere continually surcharged with dust is a seriously harmful matter.

Suspicion, almost amounting to assurance, is also now entertained that dust plays an important rôle in the spread of typhoid fever. This probability was referred to and commented on by Dr. Victor Vaughan at the time of the Spanish-American War, and the theory has been emphasized and its likelihood accentuated by the result of experience gained by British Army surgeons during the long campaign in South Africa—a country particularly notorious at one season of the year for its clouds of dust and multiplicity of flies.

Dr. Tooth and others have definitely stated that, in their opinion, the scope of an epidemic of enteric fever is greatly augmented by the agency of dust. This being so, it might naturally be thought that extreme care would be taken in large cities to keep the dust pest within reasonable limits. Such, unfortunately, however, is not the case in New York, where "the powers that be," with a cynical disregard for the comfort of, and a callous carelessness regarding the health of the inhabitants, allow the dust—that is now so plentiful in the city—to be wafted or swished around by every breeze or wind that blows. The dust is omnipresent and penetrating, and constitutes a veritable plague of Egypt. It invades street cars, railway cars, and houses; no place is safe from its inroads.

There are side streets in New York at the present time in which building operations are going on that are almost impassable, and in which the denizens dare not open their windows for fear of the dust.

There is no exaggeration in saying that in no city outside of the United States would its inhabitants patiently bear the conditions now prevailing in New York as do the long-suffering citizens of the metropolis of the western hemisphere.

Why are not steps taken to abate the nuisance and menace to health produced by the extensive building operations progressing at the present time in New York City.

The Lancet Commission on Glycerinated Calf Vaccine Lymphs.

At the present juncture, when accusations are being levelled at glycerinated calf as a probable cause of tetanus, the report on the subject by the Lancet Commission comes appropos.

The first report by this Commission was published in the *Lancet* on April 28, and attention was drawn to the fact that although the lymphs then on the market differed very greatly as regards their bacterial purity, they were, taking them as a whole, eminently satisfactory. The bacterial purity of all the samples examined was found to be high, while those in the first class retained their vaccinal activity.

The report given in the issue of June 7 is even more satisfatory than that of April 28, with the exception that the anacrobic organisms are much more numerous than they were on the first occasion.

The Commissioners conclude, as they did two years ago, that "there is still room for improvement, since there is yet much diversity in respect to the degree to which extraneous bacteria are present."

The results of the investigation carried on by the Commission, says the writer in the *Lancet*, appear to indicate still more clearly that the efficacy of the vaccine is not necessarily impaired in those cases in which the glycerination has been carried to such a point that practically all the bacteria have been eliminated. It cannot, however, be insisted too strongly that agents for the sale of vaccine lymphs should be careful not to send out lymph of which they do not know the exact date, and must avoid sending it out after the date given by the manufacturer as limiting its due period of action. The Commissioners have had placed at their disposal the results of a large number of cases in which various vaccines have been used, and they are even more firmly convinced than they were by the results of the earlier investigation that the freer the lymph is from extraneous pyogenic and other organisms, the less marked will be those inflammatory concomitants which are so familiar to all vaccinators.

Vaccination by glycerinated lymph is a great improvement on former methods of performing this operation, but vaccine virus prepared in this way is not entirely free from defects. The greatest possible care is necessary in its manufacture, so that the finished article may be, as far as human skill can devise, free from contamination. The preparation should also be used while fresh.

The Diagnosis of Malaria.

Dr. Patrick Manson has contributed to the *Lancet*, May 17, a useful article on the diagnosis of malaria. He begins his remarks by saying that slipshod diagnosis is not to be commended, but somewhat spoils the point of this statement by declaring that really after all a mistaken diagnosis is no great matter, so far as the interests of patients are concerned, in the vast majority of diseases, as we possess little or no power for good. There are, however, he admits, a few diseases over which we can exercise absolute or relative control, and of course with these it is of the utmost importance that a correct diagnosis be made—malaria, for instance. Dr. Manson draws attention to the fact that such is the exaggerated idea of the insalubrity of tropical countries, of the universal prevalence of malaria in them, that a very large proportion of the febrile and even non-febrile diseases coming from them are diagnosed and treated as malarial. Dr. Manson asserts that nowadays no mistakes should be made with regard to the diagnosis of malaria, and proceeds to recapitulate and accentuate the principles of such diagnosis.

He divides the pathognomonic indications of malarial infection as follows: (1) The clinical; (2) The therapeutic; and (3) The microscopical.

Through lack of space it would be impossible to deal with each of these divisions, so thus it must suffice to touch briefly upon the clinical diagnosis of malaria.

There is only one clinical symptom, according to Dr. Manson, that justifies a positive diagnosis. This is periodicity—periodicity of a particular type—tertian or quartan periodicity—a rhythmical recurrence of symptoms every forty-eight or seventy-two hours. In no other morbid condition are these to be found, and whenever they are well marked malaria is present.

Quotidian periodicity, although it often occurs in malaria, is no certain symptom of the disease. It is general in almost all febrile attacks. Therefore quotidian periodicity is to be absolutely disregarded as diagnostic of malaria, while quartan and tertian periodicity may be taken as a sure basis of the malady.

There are undoubtedly more mistakes made in diagnosis of malarial fever in this country than in England, for the reason that a much larger number of cases are encountered. Many medical men who are called in to treat a patient suffering from a febrile complaint in which one of the prominent symptoms is a daily recurring fever, term it at once malaria. Dr. Manson shows that this diagnosis is incorrect, and further points out that it may be and often is attended with inconvenient results, insomuch as the treatment is governed by the diagnosis.

If the malady is malaria quinine will cure it, if not the drug will do no good and may probably do some harm.

Studies of Snake Poisoning.

Dr. Simon Flexner and Dr. Hideyo Noguchi are publishing, in the *Journal of Experimental Medicine*, investigations made by them on "Snake Venom in Relation to Hæmolysis, Bacteriolysis and Toxicity."

Dr. Fraser of Edinburgh and Dr. Calmette of Paris have made valuable researches into the matter, and both have discovered an antevenim.

Drs. Flexner and Noguchi found that red and white corpuscles are destroyed by snake venom. In order to obtain a sufficiently large quantity of leucocytes for experimental purposes, a substance having a chemical attraction for the leucocytes was injected into the pleural and peritoneal cavities of the rabbit. The fluid in these cavities was found to be—in the space of from eighteen to twenty-four hours—rich in leucocytes, and could be drawn out by a capillary tube without fatally injuring the animal. The leucocytes were then placed on the warm stage and microscopically examined. Solutions of venom were used varying from 10 per cent. to .002 per cent., which was the weakest effective solution.

Only the large granular cells showed the usual migratory motions, and these were first affected by the poison. The largest ones were the first to be affected, and in the course of six hours most of them had disintegrated. Two to 10 per cent. solutions of cobra venom instantly stopped the movement of the leucocytes.

Rattlesnake venom acts more slowly—a 2 per cent. solution requiring two hours to dissolve corpuscles, while a 2 per cent. solution of cobra venom dissolved the white corpuscles in thirty minutes. The investigations in regard to the bactericidal properties of snakes were especially interesting.

The disease-resisting germs contained in blood serum were shown to be affected by snake venom.

When bacteria were injected into the blood of animals in a normal condition, these disease-producing germs were wholly destroyed, but when animals which had been previously treated with snake poison were thus inoculated, they exhibited much loss of bactericidal power.

Cobra venom was in all respects shown to be the most actively destructive. Concentrated copperhead venom was also found to possess strong bactericidal destroying properties.

The bactericidal power of many normal blood sera can be destroyed by a certain amount of any venom, but this is only possible when the venom will unite with the bactericidal elements in the serum, otherwise its destructive action is nullified.

Calmette's antevenim was tested and came out of the trial in a satisfactory manner, as it was demonstrated that it will neutralize venom and destroy its dissolving and antibacteriolytic properties.

Immunity can be conferred on animals by means of the venom, when they will yield an antitoxin, just as an animal is rendered immune by the action of bacteria, thus showing that the venom poisons are closely related to the toxins of bacteria and of the higher plants.

The researches being conducted by Drs. Flexner and Noguchi are of great scientific importance as well as of a definite practical value.

The Medical Aspects of the West Indian Islands.

The islands of the West Indies may be compared, not inaptly, to tropical fruit, beautiful to look at, luscious and tempting, but, when opened, generally devoid of fine flavor, and too often rotten at the core.

There are no more beautiful regions on the face of the earth than are the West Indian Islands.

Mountainous, covered with a luxuriant vegetation, surrounded by blue sea, where the climate is one long summer, it might be imagined that they would provide an ideal home for the invalid.

Dr. Louis Vintras has written in the *Hospital*, May 31, an account of the West Indian Islands, considered from a health standpoint. He instances Kingston, Jamaica, as a typical West Indian town, built on marshy soil, with its sultry, moist, lowering heat, and above it the free slopes of the mountains, rising to shaggy crests, which cut a clear outline across the blue sky—below the heavy miasma-laden air; above the light, pure atmosphere, the fresh breezes, and the promise of health.

The above description, it is said, applies to most West Indian towns. They are built on the low, swampy, malaria-stricken grounds, and are, consequently, unhealthy, while the heights revel in pure health-giving air.

Both Martinique and St. Vincent—the ill-fated islands lately wrecked by volcanic eruptions—were considered among the most healthy of the group.

Trinidad, Dr. Vintras says, is the most unhealthy, and, in Port of Spain, the carrion crow is protected by law to act as a general scavenger.

On the whole it would seem that, until conditions are changed, it would be unwise to recommend the majority of the West Indian Islands as health resorts.

News of the Week.

The Condition of King Edward VII.—The latest reports from Buckingham Palace are to the effect that King Edward VII. is slowly progressing toward recovery, and the wound is healing, as is proper in such cases, from within outward. So far no complications, local or general, have manifested themselves, and the outlook is exceedingly gratifying.

Pay of Fire Department Surgeons.—In the old city of New York the salary of a surgeon in the fire department was $2,000 a year, and, according to the charter of the consolidated city, the compensation was to remain the same. But, in 1898, the Fire Commissioners and the Board of Estimate and Assessment concurred in setting aside $9,000 as compensation for three surgeons to the fire department for that year. The surgeons contended that that action fixed their salary at $3,000 per annum each, and they brought suit against the city for the increased amount and arrears since 1898. The Supreme Court, however, recently found against them, holding that the provisions of the charter were final and, moreover, came into effect prior to the action of the Commissioners in raising the surgeon's salaries; so the surgeons get only their $2,000—a small enough compensation in truth, yet one that many would be glad to accept for the service rendered.

A Murderous Nurse.—Mention was made in these columns some months ago of the arrest of Miss Jane Toppan, a professional nurse in Massachusetts, on suspicion of having killed several of the patients under her care. She was indicted for the murder of three persons, but was suspected of having killed eleven. On the trial recently concluded, she was found not guilty of murder in the legal sense, but was adjudged insane and committed to the Taunton Insane Hospital. At the conclusion of the trial the woman denied that she was insane, but said she knew she was doing wrong, yet could not help committing the crimes. She said she had killed, not eleven, but thirty-one persons, many of whom were intimate friends; others the patients of physicians who had employed her on account of her skill in nursing. The poison used in each case was morphine.

Outings for the Aged.—It is stated in *Charities*, that an association has been organized in Baltimore to provide outings for aged people. Persons more than fifty-five years of age will be sent into the country for a week's vacation at cottages already provided. In addition to sending away as many persons as their funds will allow, the association will arrange car and carriage rides for those who must remain in the city.

Dr. William M. Leszzusky has been appointed consulting neurologist to the Harlem Hospital.

The Philadelphia County Medical Society at its June business meeting unanimously instructed its delegates to vote for its ex-President, Dr. William M. Welch, as president of the Medical Society of the State of Pennsylvania.

The Prevention of Venereal Disease.—The following resolution, introduced by Dr. Ludwig Weiss of New York City, and seconded by Dr. L. D. Bulkley of the same place, was unanimously adopted by the Section on Cutaneous Medicine and Surgery of the American Medical Association at its meeting June 12, 1902; and a committee, consisting of Drs. L. Weiss and Dr. L. Bulkley of New York and Frank H. Montgomery of Chicago, was appointed to present the same to the Section on Hygiene and Sanitary Science of the American Medical Association, for coöperation:

"*Whereas*, There is a burning necessity to check the spread of venereal diseases, and assuming that the States cannot with impunity ignore the condition, it lies in the province of the medical profession to discuss and recommend to the respective State legislatures and municipalities means, not regulamantative, but social, economic, educative, and sanitary in character, to diminish the danger from venereal diseases.

Resolved, That the Section on Cutaneous Medicine and Surgery of the American Medical Association invite the Section on Hygiene and Sanitary Science to coöperate with the Section on Cutaneous Medicine and Surgery in bringing about a propaganda in the different States, looking toward a proper recognition of the dangers from venereal diseases and to arrange for a national meeting under the auspices of the American Medical Association for the prophylaxis of venereal diseases, similar to the International Conference for the Prophylaxis of Venereal Diseases, which meets again this year at Brussels, under the authority of the Belgian government at Brussels."

The House of Delegates of the American Medical Association, in its meeting June 13, 1902, has acted favorably upon this resolution, and appointed a committee of six to study the matter and to report to the Association at its next year's meeting. These are the members of the Committee appointed by the Chair: Henry D. Holton of Brattleboro, Vt.; George M. Kober, Washington, D. C.; W. H. Sanders, Alabama, from the Section on Hygiene and Sanitary Science, and Ludwig Weiss, New York; L. Duncan Bulkley, New York; Frank H. Montgomery, Chicago, from the Section on Cutaneous Medicine and Surgery.

Cholera in the Philippines.—From the date of the first appearance of cholera in Manila some months ago to the middle of June there have been registered 1,530 cases with 1,236 deaths in Manila, and 7,369 cases with 5,440 deaths in the provinces. Ninety American soldiers have died all within the month preceding the date of the report. Nearly every case among the troops can be traced to neglect of the army rules regarding the drinking water.

American Association of Life Insurance Examining Surgeons.—At the annual meeting of this society, held under the presidency of Dr. James H. Stowell of Chicago, in Saratoga, on Monday, June 9, the following officers were elected: *President*, Dr. Charles Lyman Greene of St. Paul, Minn.; *Vice-Presidents*, Drs. W. B. DeGarmo of New York, James Taggart Priestley of Des Moines, Ia., P. Maxwell Foshay of Cleveland, Ohio, and Wm. A. Adams of Fort Worth, Texas; *Secretary* and *Treasurer*, Dr. J. J. Morrissey of New York.

The Hospital Corps Company at Gettysburg.—Plans are being made to have the U. S. Army Hospital Corps Company, stationed at Washington

Barracks, D. C., march to Gettysburg, Pa., and take part in the exercises of the Pennsylvania National Guard, in camp at that place during the week beginning July 15. The Hospital Corps Company, which is 125 men strong, will give daily drills in first aid, transportation of wounded and field hospital establishment for the benefit of the similar branch of the service of the National Guard.

Major Walter Reed.—In addition to the degree of LL. D., recently conferred upon him by Harvard University for his discoveries relative to the prevention of yellow fever, Major Walter Reed, Surgeon, U. S. Army, has also received the degree of LL.D. from the University of Michigan.

The Medical Missionary Society in China has decided to establish a medical college for men in connection with the hospital operated by the society in Canton. The sum of $50,000 is to be expended upon its organization and equipment.

The Woman's Medical College of Pennsylvania.—Dr. Anna E. Broomall has resigned as head of the Department of Obstetrics. Dr. Ella B. Everitt, at present resident physician in the Woman's Hospital, has been elected to the Chair of Gynecology in succession to Dr. Hannah T. Croasdale, recently resigned.

The State Board of Pharmacy.—An association of retail druggists recently applied for a mandamus to compel the election of a new set of members of the State Board of Pharmacy for the Eastern District, contending that all the present members had been legislated out of office by an amendment to the Pharmacy Law passed by the Legislature last winter. The application was denied, and in the ensuing election Mr. Clarence O. Bigelow was chosen to succeed himself.

Cholera in Manila.—With respect to the outbreak of cholera in Manila, a report, dated March 30, recently received, says: "I think cholera has existed for some time in Canton, and was brought here in vegetables imported into Manila from that city. Assistant Surgeon Kerr, on duty in Hongkong, cabled, March 3, that cholera was present in Canton and immediately stopped the shipment of all articles prohibited by the regulations from cholera-infected ports, but evidently vegetables admitted prior to knowledge of the disease in Canton introduced the infection. If information had been received one month sooner, no doubt the introduction of the disease could have been prevented. The first cases occurred on March 20. The city at that time was already divided into sanitary districts, and inspection work was daily carried on in order to detect any plague cases that might occur, and a detention camp, large enough to accommodate 2,000 people, had recently been completed. In addition, new stations were established in all sections of the city, the number of inspectors and physicians increased many times, and the inspection work carried on with vigor night and day. Every case of illness was examined, and all that were suspicious were sent to hospital. Cholera cases were sent to the cholera hospital, and all contacts and suspects sent to the detention camp, the infected house being at once disinfected, closed, and placed under guard. In this way the cases were secured early and contacts caught before they had time to escape. In a few days, the number of cases continuing to increase in the Farola district, the property was appraised and burned, thereby destroying the worst foci. Immediately after this the daily number of cases commenced to diminish. A cordon was immediately thrown around the city, ferryboats and passenger trains were stopped, and all passengers going to the neighboring provinces, either by rail or boat, were required to secure permits from the board of health. All old wells and cisterns in the city were closed, and a guard was placed on the river supplying the city with water, in order to prevent pollution and infection. All green vegetables in the city and markets that were considered as liable to convey the disease were bought and destroyed. People were advised by circular of the precautions to be taken, and distilled water was furnished free at different stations throughout the city. The quarantining of the city against the provinces was immediately put in effect, in order to prevent an exodus of people, and to prevent, if possible, the spread of the disease to other places in the islands."

Obituary Notes.—Dr. William N. Fisher died at the Columbia University Hospital in Washington, on June 26, as the result of a fall down the elevator shaft of that institution the night before. He had called to see a patient, and on leaving walked into the open door of the elevator shaft. His skull was fractured in five places and he did not regain consciousness. Dr. Fisher was born in Richmond, Va., and moved to Washington in 1876.

Dr. John T. Winter died at his home in Washington on June 22, at the age of sixty years. Dr. Winter was born in Petersville, Md., and went to Washington at the beginning of the Civil War. He was a graduate of the Georgetown Medical School in 1870. He was one of the founders of the National University Medical School and a member of the attending staff of several hospitals in Washington. He was President of the Board of Commissioners of Pharmacy of the District of Columbia and a member of the American Medical Association, the District Medical Association, and the District Medical Society.

Dr. Frederick W. Thum of Newark, N. J., died at his home in that city on June 27, at the age of thirty-seven years. The cause of his death was pyæmia, following inflammation caused by the scratch of a pin. He was a graduate of the Medical Department of Columbia University in 1891.

Dr. Ernest Potter Jenks died at his residence in this city on June 25, of Bright's disease. He was born at Boston, May 18, 1866, attended the Brookfield (Mass) High School, and after graduation from that institution entered Brown University, from which he was graduated in 1889. While there he took a special course in natural history under his uncle, the professor in that department, assisting him in many ways, and on graduating presented to the Jenks' Museum, founded by his uncle, a number of fine specimens prepared and mounted by himself. He was reported to be one of the best amateur taxidermists in this country. Dr. Jenks was graduated from the College of Physicians and Surgeons in 1898. He was connected with the Demilt Dispensary as assistant house surgeon, and also had charge of the class in diseases of the heart and lungs; he was also an assistant physician at the Vanderbilt Clinic. Dr. Jenks was a man of great natural abilities and a conscientious student, and his literary attainments covered a wide range. A genial disposition won him many friends among his fellow practitioners and outside of the profession. A widow survives him.

Dr. Benjamin Andrews died at his home in Brooklyn on June 26. He was born in this city in 1820, and graduated from the College of Physicians and Surgeons in 1847. After practising his profession for some years he retired, and devoted his attention to his property interests.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

GENERAL MEDICAL COUNCIL AND ITS APPROACHING BANKRUPTCY—LEPROSY—COLOTOMY FOR COLITIS; AFTER HISTORIES—SMALLPOX—POLYCLINIC—THE CORONATION AND THE HOSPITAL FUNDS—PRELIMINARY EDUCATION—MIDWIVES' BILL—FATAL FIRES—MUZZLING DOGS—DEATH OF DR. COTMAN.

London, June 6.

The Medical Council has once more shown itself unable or unwilling to conclude its summer session within the week, and so carried its business over the Sunday and did not wind it up until Tuesday afternoon. This may suit some members who like the opportunity of a trip to London at the expense of the profession, for you will remember they are paid five guineas a day for attendance and their hotel bills are defrayed for them. This may seem a trifle but deserves notice, because most of the Fridays and Saturdays' sittings were spent in discussing the financial straights to which the Council has been reduced by its reckless accumulation of yearly recurring deficits. A further sum of more than £1,500 has to be added to the Council's debt—that being this year's excess of expenditure over its income. The annual deficit for the past seven years has averaged £1,200.

Even these learned representatives of colleges and universities see that this cannot go on forever, but they seem sorely puzzled as to the remedy. One proposed to leave the President to carry on the business as economically as he could. Another wanted a committee to consider what economies are possible. The first proposal was properly rejected; as to the second, the Report of the Finance Committee was before the Council and that contained definite suggestions.

One of these was to impose a registration fee on students, but, while registration is only optional, that would not produce much. Another suggestion was to increase the fee for registration of practitioners, and this found favor with the Council. Mr. Horsley advocated an annual payment by practitioners, but it was naturally contended that such a charge would render the Council unpopular, and that on going to Parliament they would be required to show that they were doing good work and doing it economically—two requirements in which I think they would certainly fail, and, as one member remarked, the question might be raised whether it was "worth while to pay for more of this sort of thing."

The analogy of solicitors, who pay an annual sum, is not exact. A good lawyer who cannot establish a connection of his own, can earn a respectable income in another's office. Not so a doctor who falls on evil times. Medical assistances scarcely give bread and cheese. To a successful surgeon, like Mr. Horsley, an annual fee may be a fleabite. I know some men on whom it would be a serious tax.

One member made the most sensible suggestion of the sitting, viz., to reduce the number of members of the Council, a plan which would assuredly add to its administrative efficiency and materially diminish its expenditure not only by the fees and hotel bills of members, but by curtailing the speeches which have been calculated to cost about a guinea a minute—rather a large price for the resulting disputation with which the council-chamber so often resounds.

At one stage of the proceedings a member remarked that they had considered economies which might reach £200 a year, but the fact remained that they had spent £200 in discussing that saving. Another member declared it would be better if they would circumcise their tongues.

Eventually the Council decided to suspend the sinking fund and prepare a bill for Parliament to enable them to raise the registration fee. As to this, Mr. Brown made the suggestion that as they had already two or three bills in hand they might as well amalgamate all and endeavor to get a complete reform. There was too much common sense in this idea for the Council to like it.

As an earnest of its economy, the Council afterward appointed visitors of examinations at five guineas a day with traveling and hotel expenses.

On Tuesday the Midwives' Bill was discussed, and Mr. Brown carried a resolution against it; but I fear this will have no effect, for the report stage of the bill is down in the House of Commons.

Two communications on leprosy were read at the Medico-Chirurgical Society's last meeting and are to be discussed at the next. One was by Mr. T. J. Tonkin, and was concerned with the disease as he observed it in the Soudan and Northern Nigeria—an area of some 500,000 square miles—over which it is very common.

Mr. Tonkin is satisfied that clothes are there the chief vehicles of contagion—the dirty habits of the Soudanese lending themselves to this.

The native cloth is woven in narrow strips, which are sewn together to make a garment. Rich persons will buy their clothes new and sell or give them away when soiled. A single robe may thus have a number of owners before it is quite worn out, any one of whom may have been a leper. Even when stiff with exudation the natives do not think it necessary to wash them. They would wear them day and night, and rolling about on the hard-matted surfaces, which serve them as beds, they would have nothing between these clothes and the provinces of their bodies, on which usually the first signs of leprosy appear. Bites of mosquitos or vermin or a scratch would still further facilitate the entrance of the baccillus. Predisposition to leprosy Mr. Tonkin referred to diet defective in nitrogen, and said this was characteristic of the diet in every known leper district. The weakness of the peripheral tissues in the low-class members of tropical races is well known. The ulcers which so often follow insignificant injuries to the skin in India is an example. Deficiency of nitrogen in the dietary is not the only factor, but Mr. Tonkin regards it as the most important—the other accidents of the patients' life might contribute to break down the resistance of the entrance of the baccillus. As to heredity, out of 220 of his cases, Mr. Tonqin could only trace it in eighteen, and therefore did not regard it as an important, still less, as a necessary factor.

The other paper was by Mr. Jon. Hutchinson, F.R.S., who has lately returned from South Africa, where his view as to the fish theory has been confirmed. This, of course, directly traverses the view expressed in the other paper. Mr. Hutchinson argued that the disease was unknown in South Africa before the Dutch occupation, and that many cases now arise *de novo*, especially in the Kaffir kraals, where it is then communicated from person to person and, particularly, to young children. He thought the irregularity of the communication suggested that it could not be by inhalation or by any form of skin inoculation. He suggested that the bacillus entered by the stomach. It might be taken in by eating food direct from a leper's hand—this he called "commensal communication"—and this, in conjunction with the fish production hypothesis, he thought would account for all the difficulties.

Next week these papers are to be discussed and, I hear that Dr. Hansen of Bergen is expected to be present and join in the debate.

The after-history of cases is too seldom obtainable. Dr. H. White and Mr. Golding-Bird have reported to the Clinical Society such history of three cases of right lumbar colotomy performed several years ago in which the artificial anus was subsequently closed. Two of the cases (one membranous colitis, one chronic dysentery) were quite cured. The third remained quite well for eighteen months after the closure but then relapsed. It was suggested by the authors that in all cases the artificial anus should be kept open for a long time—in their cases it had been so from one to two years. They thought that in severe cases it might be kept open for ten years. Irrigations they thought harmful. This last point was questioned by Dr. Percy Kidd, who said he thought they had been useful in a recent case.

Dr. Sidney Coupland asked if the operation could be satisfactorily performed on the insane, as colitis caused 10 per cent. of the mortality in large asylums. As to this, Mr. Golding-Bird expressed his willingness to colotomize any insane patients, the after-treatment falling on Dr. Coupland.

The smallpox admissions have varied during the week from sixteen to thirty-three per day. There are still more than 1,300 cases in the hospitals. The case mortality, including infants, is computed to be 16.7 per cent.

The Polyclinic dinner was held last evening, the object being to aid the finances.

London, June 23, 1902.

The King's sympathy with hospital work, long well known, has received another striking illustration this week. A meeting was called by the Lord Mayor at the Mansion House to determine the nature of a gift from the people to the King. The City, the Court, the Legislature, the Church, dissent and empire, were all represented. A letter was read from the King's secretary, in which it stated that among many benevolent schemes for celebrating the coronation "none appeals more deeply to His Majesty than that for augmenting the Hospital Fund which was instituted by him in 1897 when he was Prince of Wales, in commemoration of the Diamond jubilee of the late illustrious queen, and the welfare and prosperity of which the King has always watched with the greatest and most unfailing interest."

The Lord Mayor said £55,000 had already been received, including £1,000 given in pennies by the laboring classes. The Duke of Fife said it was an insoluble mystery to him that London had allowed her hospitals to get into such a deplorable state, and pointed out that they are not the concern of London only, but the universities of medicine, not beneficial to the poor alone, but to the rich, as in them men acquire the skill and practice which enable them to deal with the diseases of rich and poor alike. The Bishops of London and Winchester, the Chief Rabbi, Lords Glenesk and Strathcona, and other representative men having spoken, the plan was enthusiastically adopted, and the Lord Mayor's Fund is now a national one.

Here is another illustration of the King's interest in his hospital fund. A difference of opinion in a town council as to the propriety of devoting to the fund the money which would otherwise be spent in an address was referred to the King's secretary, who replied that "His Majesty cannot help thinking that altogether it would be more satisfactory were the corporations to contribute to his London hospital fund, instead of forwarding addresses to him." Another fund for the same purpose is claiming attention, for Hospital Sunday is near, and it is hoped the collections will be worthy of the coronation year. The *Lancet* has issued its usual supplement on behalf of the fund and by way of change in the appeal gives letters and statements from grateful patients. The average receipts of this fund for the last five years have been £48,326. This year it is hoped more than double that amount may be raised. Last year there was a deficiency of more than £250,000, which swallowed up all the legacies. All the hospitals are also making their own special appeals for help.

The deputation of the British Medical Association was duly received by the Education Committee of the Medical Council, and its statements promised consideration.

The object of the deputation was to persuade the Council to raise the standard of preliminary education. The committee were inclined to think they had done enough in this respect, but it may be pointed out that the age limit and examination are now actually lower than the committee themselves proposed in 1898. This is the result of the Council's inveterate habit of asking opinions and making recommendations instead of regulations. In this case they asked the advice of some so-called educational experts, and received a report which contradicted itself, not an unusual thing with that sort of "expert." So now a boy sixteen years old, who ought to be at school, may, if his parents are foolish enough to let him, begin professional study. The Association wants the age raised to seventeen. No one doubts that eighteen would be better, with an examination suited to that age. It has been objected that this would restrict the ranks of the profession and so inconvenience the public. It really looks like contemptible hypocrisy for these sleek councillors to pretend they have never heard of the bitter cry of their poorer brethren about the overcrowded state of the profession.

Most of the councillors are connected with hospitals and schools. Is it possible they are blinded by the competition of these institutions for pupils? The suggestion to postpone the question until the secondary education of the country has been placed on a better footing by Parliament is just of the kind to commend itself to the dilatory element of the Council. And this leads to another aspect of prelimina,y education. The London University, which long ago killed Greek, under its new organization has attacked Latin, which is now to be made an optional subject and the advocates of so-called practical and modern education clap their hands while one of them gravely proposes to institute a degree in commerce! When "the butcher, the baker and candlestick-maker" become university graduates, the physician and surgeon may be content with the diplomas of the corporations which ask a "little Latin and less Greek."

Much nonsense is being talked about eight years being spent on dead languages and the small return in ripe scholarship. No one expects a boy of eighteen to be a ripe scholar, but there is no reason why he should not have learned the elements of Latin and Greek as well as two living languages. That would prepare him for entering either of the professions and pursuing what he found most useful or most to his taste.

The Midwives' Bill duly passed the report stage—it may be said to have been forced through by the determination of its advocates, stimulated by the outside pressure of those women who pose as defenders of the rights of their sex. But with all this some amendments were carried in the teeth of official opposition. The Home Secretary, with the fear of wealthy women before him, begged the House to pass the bill this session as it stood and reserve further action for another. But this legislation by instalments did not find favor, naturally enough, for the House is always laboring under a plethora of bills. The plea of protecting poor women in their hour of need, so pathetically dilated upon, was obviously mere pretence, for the greatest resistance was offered to an amendment forbidding women to practice midwifery unless registered under this act. The amendment was carried with a period of grace until 1910. So if this becomes a law we shall have all the present midwives legalized and eight years hence protected. In fact, as was admitted in the House, though so many denials have been made outside, the bill is creating a new profession for women. That new profession must for many years consist of uneducated members, some with absolutely no training, and some with three months in a lying-in hospital. And these will be a protected inferior female doctor. Can any one credit the pretence that they will not encroach on the practice of medicine, especially in districts where the doctor can scarcely earn a living? And this is the plan supported by obstetricians and other leaders against the starving general practitioner! The bill is down for its third reading; that stage is mostly a formality and further opposition must be in the Lords, but little can be expected now from those who have been thus far apathetic while their own interests are at stake.

Some indignation is expressed at the indifference of the government to the loss of life from fires occasioned by lamp accidents. It is said that low-flash oil is generally the cause. Questioned in the House, Mr. Ritchie said that he was not convinced that raising the standard would diminish the number of accidents, and so the holocaust goes on, while a careless minister takes no steps to convince himself of the danger of low-flash oil. I know it is said that the lamps are equally to blame. But if human life is as important as we pretend, both causes might easily be eliminated by legislation. Can it be that legislators are interested in the low-flash oil trade?

More firmness has been displayed in respect to muzzling. Worried to make exceptions for the selfish fashionables who pathetically plead that they cannot leave their pet dogs behind when they take a trip to Paris, Mr. Hanbury replied that the government could make no exceptions, as "no loophole should be left for the spread of so terrible a disease as rabies."

The death of Dr. J. S. E. Cotman while on a cycling trip is calculated to warn enthusiastic athletes of advancing years. He left home on the 26th ult., and his body was found by the roadside twenty miles away between two and three hours afterward. His bycicle was standing against the fence, and it looked as if, feeling faint, he had got off and laid down to rest. He was sixty years of age, and had for many years taken an active part in London municipal work, being an influential and highly esteemed member of the Common Council of the city.

STEVENSON AND SYMONDS AT DAVOS.

To the Editor of the Medical Record:

Sir: In a recent issue (May 17) of your valuable journal, while discussing the treatment of consumption in high altitudes, you incidentally give credit to Robert Louis Stevenson for having had "something to do with rendering Davos popular." I do not wish to discuss the relative merits of high altitudes and lower levels in the treatment of this disease further than to point out the fact that many physicians are to-day inclined to deny any specific influence or advantage to the former, while but few could be found ten years ago who did not insist upon such difference. My object in sending this communication is rather to call attention to the fact that the popularity of Davos, both in England and in this country was due more to the efforts of the distinguished writer, biographer and critic, James Addington Symonds, than those of Robert Louis Stevenson, or of any other layman or literary man who spoke from personal experience with the disease and the resort. Symonds' visit not only preceded Stevenson's by more than three years, but he had already been contributing articles on the climate and treatment at Davos to the *Fortnightly Review*, the *Cornhill Magazine*, and the *Pall Mall Gazette*, which were published later in book form under the title: "Our Life in the Swiss Highlands." Symonds reached Davos in August, 1877, Stevenson not until November, 1880; in fact the latter's biographer says that "the great feature of the place for Stevenson was the presence of John Addington Symonds." Stevenson himself says in one of his letters: "Beyond its splendid climate, Davos has but one advantage, the neighborhood of J. A. Symonds." Your readers may be interested in some quotations from Symonds of a medical nature—although these cannot compare with his marvellous word pictures of scenery, color, and life in the Alpine highlands. He writes: "Accustomed as we are to think that warmth is essential to the satisfactory treatment of pulmonary complaints, it requires no little courage to face the severity of winter in an

Alpine valley, where the snow lies for seven months, and where the thermometer frequently falls to 10° or 15° F. below zero. Nor is it easy, by any stretch of the imagination, to realize the fact that, in spite of this intense cold, the most sensitive invalids can drive in open sledges with impunity, expose themselves without risk to falling snow through hours of exercise," etc. Again: "The worst symptoms of pulmonary sickness, fever, restless nights, cough, blood spitting and expectoration, gradually subside by merely living and breathing." And finally: "Not only the cases recorded in technical treatises, but the testimony of many persons with whom I have conversed upon the details of their cure, together with my own experience based upon a comparison of Davos with Italy and the Riviera, convince me that it is the soundest surest, and most radical system as yet discovered."

As is well known, both men finally succumbed to their disease, Stevenson having spent but two winters at Davos, and Symonds about twenty.

ALFRED MEYER, M.D.

801 MADISON AVENUE, NEW YORK.

Progress of Medical Science.

The Boston Medical and Surgical Journal, June 26, 1902.

Some Cases of Malaria Accompanied by Acute Abdominal Symptoms.—James M. Jackson reports a number of cases of malaria in which the chief symptom was abdominal pain of such intensity as to warrant the diagnosis of peritonitis or appendicitis. It is not uncommon to have some abdominal pain, at the time of the chill, but it is very unusual to have severe cramps in the abdomen preceding, as in one case, for three weeks the onset of the chill. Examination of the blood and the administration of quinine were usually sufficient to establish the diagnosis.

Typhoid Spine (Spondylitis Typhosa; Perispondylitis Typhosa.)—Elbridge G. Cutler reports a case of this affection, which is a condition of the spine resembling Pott's disease, and occasionally occurs after typhoid fever, but without the deformity which follows Pott's disease. The patient complains of pain in the lumbar or sacral region, perhaps after a slight blow, or shock or jar, or independently of such injury. The chief symptoms are stiffness, of the back, pain on movement, and tenderness on pressure, the latter symptom being the least constant. In addition there are certain nervous manifestations, sometimes even hysterical. The physical examination, aside from the tenderness mentioned, reveals nothing. Fever is not usually present, unless there are other complications. The prognosis is favorable, complete recovery following in most cases, though deformity has been observed. The treatment consists of rest in bed on the back, and the application of a plaster or leather jacket, to give support.

Analysis of Twenty-six Cases of Typhoid Spine.—Frederick T. Lord says that from 1889 to 1902 twenty-six cases of typhoid spine have been reported in the literature. He gives a detailed analysis of these cases. In general, the pathology of the process seems to be a perispondylitis or spondylitis, or both. A few of the cases may be neuroses. The coexistence of a deformity and nervous symptoms in one-half of the neurotic cases suggests that all the neurotic cases may be organic as well. Localized pain was present in all the twenty-six cases. It was associated with local tenderness in sixteen. Stiffness of the spinal column was noted in eight. These symptoms, taken together with radiating pains, in ten cases; disturbed knee-jerks in eight, and the association of these two in five, with muscular spasm in other than the adjacent spinal muscles in three, and disturbed sensation in the distribution of the spinal nerves in five, suggest the involvement of the nerve roots in a periosteitis. A rise of temperature in seven, without other cause than the spinal lesion, is still further suggestive of organic trouble. The existence of kyphosis in eight cases seems to confirm the organic character of the nerve-root symptoms, and definitely to indicate bony as well as periosteal involvement.

Journal of the American Medical Association, June 28, 1902.

A Contribution to the Treatment of Pneumonia with Antipneumococcic Serum.—In this article B. W. Goldsborough collates the results in 447 cases treated by various physicians, including sixty-one cases treated with antidiphtheritic serum. Results have been as follows; total recoveries, 377; total deaths, 70; mortality, 15.7 per cent. He contributes abstracts of the clinical histories of nine personal cases. The percentage of deaths in 395 cases treated with antipneumococcic serum was 16½. Of his own nine cases two died. He has used the serum in doses of 20 c.c., repeated in eight hours if there is not a very marked change for the better. He says that one cannot expect to obtain the same results in cases of bronchopneumonia with possibly a mixed infection as in lobar pneumonia, but his experience is, nevertheless, that the serum is of great benefit in both affections.

Medical News, June 28, 1902.

The Causes and Manner of Death in Epilepsy.—William P. Spratling declares that any epileptic may die suddenly at any time. The manner and causes of death in epilepsy may be summarized as follows: (1) It may occur suddenly in any case as the result of a single seizure; (2) It may result from a series of seizures occurring in rapid succession and ending in status epilepticus; (3) It may result from an accident suffered because of a fit; (4) It may result from any of the other causes that ordinarily produce it, with a seeming preponderance in favor of diseases of the heart and lungs. As a rule, the status epilepticus should be feared when more than three or four well-marked and distinct attacks occur within an hour's time. The most vigorous treatment to prevent status should be instituted at once. Status develops entirely irrespective of the type of epilepsy.

General Enteroptosis.—Robert T. Morris, discussing this condition, says that a snug corset is a splint. The abdominal muscles under the corset become atrophied. If the corset engages the lower rib line and prevents the liver from sliding over the right kidney, as it normally does in respiration, this organ acts like a pump piston and pushes the kidney away from its loose anchorage. Corsets may be classified as splint corsets and pump corsets. During parturition the weakened abdominal muscles are apt to pull apart along the line of the linea alba. Most women suffering from general enteroptosis are invalids to a certain degree. Palliative treatment can do much for them. The corset which now cannot be dispensed with, must be applied snugly while the patient is recumbent and after the liver and kidney have been replaced as well as possible. The afternoon bloating will then probably cease. Dyspepsia will be relieved by stomach lavage. Abdominal massage and electricity properly and persistently applied will develop the abdominal muscles and will stimulate the functions of the viscera. Operative treatment is indicated in those cases in which palliative treatment is not beneficial.

American Medicine, June 28, 1902.

The Significance of Eosinophilia in Pemphigus.—John W. Coe reports the blood examinations of two cases of pemphigus. The first patient was a woman aged forty-four years. It was a case of relapsing pemphigus, extending over a period of nine months. The eosinophilia was very marked, in one examination amounting to 51.8 per cent. The patient finally regained her usual health. The second patient was a man aged forty-four years. Several blood examinations were made and the eosinophiles reached only 6 per cent. The author suggests that in such conditions an increase in the eosinophilic leukocytes of the blood may be comparable to a polynuclear neutrophile increase, as in pneumonia, and is indicative of a more favorable prognosis. This last patient grew rapidly worse and died.

The Ear from a Medicolegal Standpoint.—W. Scheppegrell believes that a careful examination of the ear from a medicolegal standpoint is indicated in a wide range of cases. In cases of violent explosions it is important to eliminate the effects of chronic catarrhal processes which may have been present but not observed. Railroad employees are required to pass an examination of their hearing capacity to avoid accident due to defective hearing, as is also the case in military service. In cases of simulation, when the cases are supposed to be bilateral, the patient is unexpectedly called, or a sudden noise is made near him, while he is carefully watched. When the deafness is claimed to be only on one side, the most efficacious method is by means of two rubber tubes, one for each ear, and both connected with a mouthpiece behind the head of the subject. By compressing the tube leading to the healthy ear the sound will be transmitted only to the other ear, and confusion soon results. An insufficient examination may result in the escape of a criminal from his deserts, or it may subject an innocent person to unmerited punishment.

Philadelphia Medical Journal, June 28, 1902.

A Case of Acute Articular Rheumatism with Pyæmic Temperature Treated with Antistreptococcic Serum.—R. J. Chipman reports the case of a woman aged twenty-five years, who, after exposure to cold wind and low temperature, had a very severe attack of acute articular rheumatism. At one time the temperature reached 105.4°. Salicylates were given, but were not tolerated by the stomach. About six weeks after the initial attack it was decided to try the use of antistreptococcic serum. After the first injection, improvement began. In less than two months after the beginning of this treatment the patient sat up, and was convalescing very rapidly. The profound septicæmic condition present at the time this treatment was instituted seemed due to some germ infection, possibly the streptococcus. It seems impossible to ascribe the sudden remission of symptoms to mere coincidence.

A Remarkable Case of Coma, Apparently Due to Acid Intoxication Sui Generis.—This case is reported by D. L. Edsall. The patient was a man aged sixty-three years. While in apparently good health, he was suddenly overcome by vertigo, followed by prolonged coma. The coma lasted about ten hours, during which time the patient was given alkaline transfusions. He exhibited during this time the symptoms and the urinary signs of acid intoxication. He then rapidly recovered and subsequently remained perfectly well, the symptoms as well as the urinary signs of the acid intoxication disappearing coincidently with his improvement. The signs of diabetes were absent at all times. The only satisfactory diagnosis that can be made in the case is that of cryptogenic acid intoxication, which was, in all probability, of gastrointestinal origin. The man's tendency to digestive disturbance, and the presence of such disturbance for some hours preceding his attack, made this source of the intoxication a likely one. The man was completely saturated with alkalies in the treatment. He was given about 75 gms. (2½ ounces) of sodium bicarbonate intravenously, and his urine, which was tested with each portion passed, remained distinctly alkaline for about seventy hours after the alkaline transfusions were given.

The Lancet, June 21, 1902.

A Case of Rabies Latent for Twenty Months.—The case reported by D. C. Rowlands is that of a powerful man of sixty-three years, who was bitten with considerable lacertion on the metacarpo-phalangeal joints of the thumb and forefinger of the left hand. The wounds were cauterized. Three weeks later the patient was sent to the Pasteur Institute in Paris, where he remained for nineteen days. He then returned home, feeling perfectly well. Twenty months later symptoms of rabies came on, with pain in the left arm and in the stomach. Soon there developed the typical symptom-complex of rabies, and the man died in forty-eight hours.

Embryological Aspects and Etiology of Cancer.—The nature of the argument advanced by J. Beard is as follows: Cancer is derived from vagrant primary germ-cells, which, instead of forming a more or less complete embryo or embryoma, skip this and give rise to a larva or phorozoon of indefinite. unrestricted powers of growth. This is, of course, purely hypothetical, but it becomes the true explanation by the following facts: On the one hand, as researches have shown, the hypothetical "verirrte Keime" or "lost germs" of pathologists not only exist, but they are numerously represented, and by things capable of abnormal development, the vagrant primary germ-cells. On the other hand, the carcinomatous nature of such an abnormal growth of a larva or phorozoon has been abundantly demonstrated by Marchand for the instances of the pernicious growth of the chorion, chorion-epithelioma. If such a chorion, the representative more or less complete of the asexual generation, when robbed of its embryo, or when it fails to form such, can—and this is established—give origin to a malignant carcinomatous tumor, the nature of cancer is clear. The vagrant primary germ-cell is the seed, while its fruit, sometimes represented by an embryoma, may, on occasion, take the form of a carcinoma.

A Case of Difficult Diagnosis with a Rare Complication.—The patient of H. J. Mackay was a married woman of thirty-seven years. It was thought at first that she was suffering from an influenza of gastroenteric type. A change in the clinical conditions led to the theory of a possible typhoid fever, but on the twelfth day of the disease the diagnosis was still in doubt. At this time signs of cardiac weakness appeared, and the patient was cautioned to avoid all exertion. While thus situated she was seized with a sudden desire to evacuate the bowels, and forgetting previous warnings, actively coöperated with the nurse by raising her hips and trunk from the bed while in the dorsal position. She was immediately seized with abdominal pain, followed by pain in both legs from the middle of the thigh downward. To this succeeded tingling in the legs and feet and soon afterward numbness and coldness of the extremities. Examination shortly afterward showed that the lower extremities were cold from the toes to the knees. The feet and the legs were pale. Pulsation was present in both femorals at the groin and in Scarpa's triangle, and the impulse was more forcible and larger than usual. Pulsation was absent in the popliteals, in the posterior tibials, and in the dorsales pedis. Anæsthesia to touch, pain, and temperature was present over the area involved. These findings and the subsequent course of the case left no doubt as to existence of symmetrical blocking of both femoral arteries. On the sixteenth day of the illness, there was a sudden fall of temperature from 101° to 97.6°. Collapse supervened, and the patient died eleven hours later.

The British Medical Journal, June 21, 1902.

Menstruation in a Newly-Born Female Child with Convulsions.—Wm. Frew reports the case of an apparently healthy child that was taken with convulsions the day after its birth. Nothing abnormal could be found on examination. The bowels had been opened, and urine had been passed. The rectal temperature was normal, but the surface of the body was cold. Small doses of chloral and bromide were given. The child improved. The next day a discharge of blood from the vagina was observed. This lasted for three days and then ceased. The nervous symptoms gradually subsided and ceased altogether with the cessation of the menstrual discharge. The child has been perfectly well since.

On the Employment of Adrenalin as an Adjunct to the Light Treatment of Lupus.—W. Allan Jamieson has used this treatment in several cases of lupus with very satisfactory results. When adrenalin in the 1 to 1,000 solution is closely applied by means of a piece of absorbent cotton wool moistened with it for ten to fifteen minutes to such a patch, the effect produced is a distinct paling of the skin 'round the lupus spot, but no great diminution of redness in the lupus area itself. Still the effect of light on the lupus spot after the employment of adrenalin is certainly greater than in those cases in which it is not used. The reaction is more quickly obtained, the tendency to blister is enhanced, there is more rapid flattening down, and the obliteration of the lupoma is accelerated.

A Gallstone Simulating Cancer.—Bernhard Morris describes this case. The patient was a man of sixty-seven years, who had had, on several occasions, attacks of hæmoptysis and hæmatemesis. There was loss of appetite, vomiting and severe pain. During the paroxysms the symptoms simulated those of intestinal obstruction. Several times he brought up large quantities of blood. Cancer was thought of, but no tumor could be detected. The attacks of coffee-ground vomiting were repeated. On one occasion he became unconscious, and after being revived by artificial respiration, he complained of severe pain in the anal region. Examination disclosed a gallstone about the size of a walnut with corrugated surface It was removed, and was found to weigh 259 gr. Since passing this stone the patient has improved rapidly, and has had no more attacks of pain.

Deutsche medicinische Wochenschrift, June 5, 1902.

Etiology of Typhoid Angina.—Ernst Bendix and Adolf Bickel report a case of typhoid fever which was complicated by a severe angina which first made its appearance during the latter part of the second week of the disease. Marked pain and swelling appeared in the affected region, and a considerable interference with respiration was caused thereby. On inspection there was seen a circumscribed indurated swelling about the size of a large bean on either side of the arcus palatoglossus. These were pierced with a sterile needle and cultures made therefrom. From these cultures typhoid bacilli were isolated. A similar swelling also developed on the uvula. The involved tissue subsequently ulcerated and appeared as a typical typhoid ulcer. Recovery took place and the course of the disease was not materially altered by the angina. This case shows that typhoid angina may be due to the presence of the specific bacillus, although in all probability such is not always the case.

Treatment of Pulmonary Hemorrhage.—Otto Niedner reports six cases which show that oftentimes pulmonary hemorrhage may be successfully treated by immobilization of the chest on the side from which the bleeding originates. This is best accomplished by strapping with adhesive plaster in the ordinary manner. The whole affected side of the chest is to be strapped beginning at the lower extremity of the lung and continuing upward over the entire shoulder and clavicular regions. In order to equalize the pressure, pads of absorbent cotton are placed beneath the plaster in the axilla and also in the infra- and supra-clavicular fossæ. The strapping should be so done as to produce the greatest equaliz pressure possible. It may be left in place for days or even weeks. It may be applied with but little inconvenience to the patient. In the six cases reported the hemorrhage was thus successfully treated in every instance. The extended use of this method is desirable in order that a more definite opinion of its exact value may be obtained.

Berliner klinische Wochenschrift, June 9, 1902.

Marriage and Venereal Diseases.—E. Lesser considers this question and the duty of the physician with respect thereto. So far as gonorrhœa is concerned, cases may be divided into three classes: The first class comprises those cases in which the patient is not engaged to be married but anticipates such an engagement. Here if subjective symptoms and gonococci are present the engagement should be postponed until complete recovery has taken place. If no subjective symptoms are present and repeated examination fails to detect the presence of gonococci, the engagement may be immediately entered into. A decision is most difficult in those cases in which no gonococci can be found, but in which threads (mucus) and leucocytes are present in the urine. Many of these cases so run on for years, and are practically incurable. In most of them the history shows numerous attacks of gonorrhœa. When the last attack dates some years back and the mucous threads and leucocytes are scarce in the urine an engagement may be permitted. In all other cases it should be postponed until improvement has taken place. In the second class of cases the patients apply for advice after the engagement has occurred. Here the same general rules should be applied as given for the first class, and the marriage must be postponed until their requirements are met. In the third class of cases the symptoms of gonorrhœa first develop after the marriage has been consummated. Here all marital intercourse should be interdicted until the requirements mentioned above have been met. While the statements here made are given with especial reference to gonorrhœa of the male the same general rules should be observed with respect to females. When we come to the consideration of syphilis the same three classes of patients as above mentioned present themselves. It should be laid down as an absolute rule that no person should marry sooner than three years after contracting this disease, during which time he or she has been appropriately and energetically treated. In all cases in which the secondary symptoms are at all severe this period should be increased to five years. In those cases in which syphilis first develops after marriage has been consummated it is practically impossible to prevent the infection of the wife or husband. In securing adherence to his advice more depends upon the tact of the physician than anything else, and each case must be dealt with according to its own particular conditions.

The Blood-Purifying Function of the Kidney.—H Strauss considers the blood-purifying function of the kidney in its relation to the excess of nitrogenous compounds, other than the albuminoids, which accumulate in the blood serum, and transudations during the course of chronic nephritis. To this end 200 cases of chronic interstitial and chronic parenchymatous nephritis were examined with respect to the quantity of such retention products in the above-named fluids. The amount of uric acid and ammonia present in such fluids is always greater in chronic interstitial nephritis than in chronic parenchymatous nephritis or in normal individuals. This increase is absolute but not relative except in cases of uræmia. The amount of salt and ashes (dry residue) varies within small limits, and shows no constant relation with either form of nephritis. The molecular concentration of the blood serum is not increased in chronic parenchymatous nephritis, and but slightly in the chronic interstitial form. The toxicity of the blood serum is greater in chronic interstitial than in chronic parenchymatous nephritis. All of these facts go to show that the method of compensation which nature employs in chronic parenchymatous nephritis is essentially directed toward the dilution of the retained products within the blood vessels, while in chronic interstitial nephritis the same result is obtained by an increase in the cardiac action and polyuria. In the latter form of the disease, therefore, the greatest importance should be attached to therapeutic measures which improve and sustain cardiac power. Nor should the same be overlooked in the treatment of chronic parenchymatous nephritis, since observation has shown that in many instances there occurs a lessening of the cardiac power coincident with the transformation of this type into the chronic interstitial form. Much has recently been written, pro and con, with respect to limiting the supply of liquids in chronic nephritis. So far as the chronic parenchymatous form is concerned, it would seem as though a sufficient amount of liquids should be allowed, since this favors dilution and assists nature in its efforts at compensation. There is no doubt but that the amount of retained nitrogenous compounds is less upon a non-nitrogenous than upon a nitrogenous diet. For this reason in chronic nephritis all nitrogenous food should be limited and carbohydrates and fats substituted therefore. A sufficient amount of nitrogenous food requisite for proper cardiac nutrition should, however, always be allowed. Sweating, purging, the removal of transudates, and blood-letting are valuable means for the removal of retained poisonous compounds. Their application to individual cases is a matter for direct personal consideration. In general, however, it may be said that the necessity for their use should be anticipated, and that they should be employed before uræmia or severe subjective symptoms demand their use.

Münchener medicinische Wochenschrift, June 10, 1902.

Concentric Hypertrophy of the Right Ventricle. Navel Cysts.—Karl Walz reports the case of a man, fifty-one years of age, who was suddenly seized with pains in the umbilical region and violent diarrhœa. The temperature and pulse were normal. Upon examination there was found protruding from the umbilicus a tumor about the size of a hen's egg, which was irreducible and very tender upon pressure. Upon questioning the patient it was ascertained that the tumor had appeared at intervals for some years previous, but had never been painful, and had always been easily reduced by the patient himself. A diagnosis of strangulated omental hernia was made and operative procedures were immediately instituted. Upon opening the hernial sac a serous fluid escaped, and further examination showed that a cyst had been opened. The same was removed and submitted to microscopical examination when it was found to be of the connective tissue type. The wound was closed and union took place by first intention.

Extensive Calcification of the Walls of a Partial Cardiac Aneurysm.—Franz v. Pessl reports the case of a man forty-five years of age who, in May, 1901, first complained of a swelling of the cervical and axillary glands. This subsided somewhat under arsenic, but reappeared in November, 1901, and was not further influenced by the drug. The pulse became accelerated, varying between 94 and 108 per minute. Marked dyspnœa developed, which was ascribed to pressure upon the trachea of some of the enlarged glands, and an operation was untertaken for their removal. The patient bore the anæsthetic very badly, and the operation was completed with difficulty. The pulse remained persistently high and death took place two days subsequently. At autopsy the following cardiac lesions, which were wholly unsuspected, were found; chronic partial aneurysm of the left ventricle, chronic myocarditis with secondary calcification of the larger portion of the wall of the left ventricle, chronic endarteritis with calcification of the descending branch of the coronary artery, also a compensatory concentric hypertrophy of the right ventricle.

French and Italian Journals.

The Presence of Fatty Acids in Water.—M. H. Cause concludes that fatty acids are found in potable waters united to the salts of lime, magnesia, and to ferrous oxide. They increase the hardness of water, and are a proof of past contamination. As long as the temperature is about 48° F., their presence does not seem to exercise any harmful influence. Above that the impurity of the water shows its effects. Consequently the same water, good in winter, becomes suspicious or bad in summer.—*Lyon Médical*, June, 1, 1902.

Anatomical Tubercle.—Hassler reports the case of a young student who, in making an autopsy on a subject with acute miliary tuberculosis, cut his middle finger. The wound was carefully disinfected and was then covered with collodion. Sometime later a small abcess appared at the spot, and this was followed by engorgement of the epitrochlear gland, and later by engorgement of the axillary glands. Ablation of the primary focus was performed, and of the epitrochlear gland. The diseased glands of the axilla were also removed. Inoculation of animals later proved the trouble to be tuberculosis. Instead of collodion in such cases, wet dressings should always be used, for one cannot be sure of complete disinfection.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, June 8, 1902.

Myxœdematous Conditions and Soft Cutaneous Fibromata.—Francesco Calderonio says that clinically, etiologically, and histologically myxœdema should be regarded as a soft fibromatous condition of the skin, similar to soft fibroma, and not as a mucous degeneration. This form of fibroma is due to neuropathic predisposition, and to a general or local infection, which may be syphilitic or due to pyogenous agents. In the treatment, simple removal is not enough, but should be followed by the application of caustics, as this will result in better resolution of the endophlebitis, and the interstitial infiltrations, and will facilitate the formation of more resistant cicatrices.—*La Riforma Medica*, June 11 and 12, 1902.

Chronic Meningomyelitis and Its Treatment.—Stefano Personali holds that this affection is a pathological entity, which is as yet little recognized by practitioners, and is confounded with other forms of disease that resemble it. He gives his reasons for this statement. As to treatment, suspension, with the usual apparatus, should be applied daily from one to four minutes a day for four days, then four minutes for twelve days, after which the patient is placed in a plaster jacket while suspended. This jacket is kept on for three months, the patient being on his back in bed. After that he is allowed to sit up in bed a little longer each day, and when he can walk a bit about the house, the jacket is removed and another one applied, which remains on for two months, the patient not being kept as strictly in a reclining position as with the first one. It is then removed and a third one made of strong muslin applied and left on for three months, which ends the treatment. The results obtained are remarkable—pain disappears in a few days, and the patient improves rapidly in every way.—*La Riforma Medica*, June 6 and 7, 1902.

The Pigments of the Organism.—Hugounenq states that there is a formation of pigments in the organism in all diseases in which there is a great destruction of the blood corpuscles. All of these pigments are rich in iron. Sometimes peroxide of iron occurs. This probably comes from the destruction of hematin. Hematin is not yet perfectly understood, in spite of the recent studies. It appears to be composed chemically of two substances, which are joined together by an atom of iron. They are rather easily separated. The first element is colorless and has no iron, while the second is colored and carries all the iron. The writer has been able to obtain different intermediary products. These are amorphous and soluble only in caustic potash. Hæmoglobin, freed by the destruction of the red corpuscles, is the seat of successive oxydations, which destroy it and transform it into a series of intermediary products.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, June 5, 1902.

A Case of Acromegaly.—Carlo Mastri reports the case of a woman of thirty-seven years, who, in 1894, suffered from a severe attack of typhoid fever, and about a year later suddenly stopped menstruating, gradually lost the power of vision, which became completely absent in the left eye, and became swollen and enlarged in body. Loss of strength, curvature of the spine, pain in the lower extremities, pain in the head, and constant somnolence were some of the symptoms which accompanied her condition, which was diagnosed as acromegaly. The thyroid gland treatment has not caused any perceptible diminution in size, but the patient states that the pains are lessened, and that she is no longer troubled with somnolence. The author holds that the pituitary gland in some way regulates the function of the thyroid, so that if it be affected the influence of the lesion will extend to the thyroid, and result in functional disorders capable of causing such a condition as is described above.—*Rivista Critica di Clinica Medica*, May 24, 1902.

Treatment of Uræmia.—Cassine declares that the intoxication of uræmia is not due to any one substance contained in the urine, but to all of the substances which ought to be eliminated from the body through the urine, but which, owing to the diseased kidneys, accumulate in the blood, thus giving rise to the condition of uræmia. In severe cases the patient should be bled if possible, as this eliminates a great deal of poison. This lowers vascular tension and facilitates the absorption of the visceral œdema. If bleeding is impossible, leeches may be applied. Artificial serum should be subcutaneously injected after the bleeding, as this supplies a fluid identical with normal serum. The best diuretic is water. Laxatives given in an intermittent manner, contribute to the antisepsis of the intestines. Those prescribed should not be too severe. Hot baths are very useful. If pilocarpine is given, the greatest prudence should be observed, as it is a dangerous remedy. A great deal can be done by these means to alleviate the sufferings of the patient.—*Le Nord Médical*, June 1, 1902.

The Different Methods of Surgical Anæsthesia.—Chaput concludes that ethylchloride is the anæsthetic of choice for small operations. It is indicated, when it is possible in patients who dread general anæthesia, and in the diathesis which are known to contraindicate general anæsthesia. It may be used in superficial laparotomies, in herniæ, and in a large number of important operations. It is contraindicated in children, in those of very nervous temperament, and in complicated laparotomies. Spinal cocainization is the method of choice for all the operations on the lower limbs, the anus and the rectum, and the genitourinary organs of both sexes. It may be used in superficial laparotomies and in herniæ. It is indicated in operations on the thorax and in difficult laparotomies when general anæsthesia is dangerous. General anæsthesia is indicated in children, the very nervous, and for complicated operations. It is the method of choice for all medium and severe operations in the suprapelvic zone in individuals who are in good condition. It is contraindicated in individuals who are not in good general condition. Ether is the best general anæsthetic, but it is unfortunately contraindicated in the old, the obese, in patients with severe cough, in operations on the face and head; it is often badly borne; the patients who have once taken it never wish it again. Chloroform is the exceptional anæsthetic. It is of use only in those cases in which other methods cannot be used. Chloroform is the antidote of ether, and *vice versa.*—*La Presse Médicale*, June, 11, 1902.

Raynaud's Disease of Hysterical Nature Cured by Indirect Suggestion.—M. A. Souques reports this case. The patient was a man twenty-seven years old, who for fifteen years had had several times every day crises of local asphyxia of the extremities, as a rule localized in the left hand, sometimes in the two hands. These were caused by contact with cold air or water, more frequent in winter than in summer; these crises were accompanied by anæsthesia and by acute pain. During the paroxysims, which sometimes lasted for an hour, local temperature dropped to 5° C. Then the color of the skin and the temperature would gradually return to normal, and the pain would cease. The vasomotor troubles showed themselves for the first time at the age of twelve years. Examination of the patient revealed manifest stigmata of hysteria, and consequently Souques had recourse to indirect suggestion. The patient was given a pill, which he was told was very powerful, in reality, it contained methylene blue. He was told that if the urine became blue he would be cured for it would show that the blue color in the hands had passed into the urine. The urine became blue and the local asphyxia rapidly disappeared. The color and temperature of the extremities remain normal, and the pain has not reappeared for fifteen days in this patient, who for three months had had eight paroxysms a day. This observation shows that there is an hysterical form of Raynaud's disease which is not complicated by gangrene. It is important to be able to detect it.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, June 12, 1902.

The American Journal of the Medical Sciences, June, 1902.

The Frequency of Heredity in Gastroenteric Disturbances.—Franz A. R. Jung, from his study of these cases, formulates the following statistics: Enteroptosis in families, 67.5 per cent.; superacidity, 62.5 per cent.; subacidity, 47.5 per cent., normal acidity, 47.5 per cent. In twenty-seven families of enteroptosis we find repeated cases, 48.0 per cent.; in twenty-five families of superacidity, 40.0 per cent.; in nineteen families of subacidity, 21.0 per cent.; in nineteen families of normal acidity, 31.5 per cent. Enteroptosis is most frequent, but superacidity presents the largest number of cases in the same family. Of forty families twenty-three (57.5 per cent.) have several cases in one family of their characteristic analyses. In other words, one family out of every two presents more than one case of digestive disturbance of the same nature. The average frequency of duplicate cases of enteroptosis, superacidity, subacidity, and normal acidity lies between 27 per cent. and 48 per cent., and is consequently 34.5 per cent.

Observations upon Recent Methods of Treating Corneal Ulcers, with Especial Reference to the Use of Carbolic Acid as a Not Infrequent Substitute for the Actual Cautery.—Samuel Theobald declares that the application of carbolic acid to a corneal ulcer is a safer and simpler procedure than its cauterization by the galvano- or thermo-cautery. In applying this acid to the cornea it is important to limit its action carefully to the affected part. The eye should be anæsthetized by cocaine, which renders the operation painless. The employment of carbolic acid is not to be regarded as part of the routine treatment of corneal ulcers. The cases in which it is called for are distinctly the exception and not the rule. When the ulcer is the product of infection with one of the less virulent bacteria, other remedies are indicated. But in the case of the dangerous ulcers—the serpiginous ulcer, the ulcer complicated by hypopion—which are commonly due to the pneumococcus and sometimes to the streptococcus, the energetic germicidal action of carbolic acid is called for and its good effects are manifested. The writer applies the acid by a pointed toothpick, on the tip of which is wound a very small quantity of absorbent cotton. The acid is applied to the surface of the ulcer by a gentle rubbing movement, which is really a sort of curettage.

Observations on the Nature of the Bence Jones' Albumin.—Charles E. Simon concludes from the reported cases of Bence Jones' albuminuria, that: (1) The presence of the substance in the urine of man usually indicates the existence of multiple new growths affecting the bones, and generally of myeloma; (2) Myeloma may apparently occur in the absence of the peculiar albuminous substance; (3) The existence of the urinary condition in association with other diseases without involvement of the bones is not as yet proved by the report of any case in which a careful post-mortem examination has been made; (4) Malignant disease of the bones, in general, may exist in the absence of the Bence Jones' albumin from the urine. The writer regards as the most characteristic general reaction, the coagulability of the substance at a temperature of from 50° C. to 58° C. The writer believes that the Bence Jones' substance is closely related to the water-soluble globulin. If further research should bear out the correctness of this view, the previously supposed identity of Noel Paton's crystalline globulin with this substance would appear to be rendered quite probable. Most observers have been of the opinion that the Bence Jones' substance originates in the diseased bone-marrow, and the writer believes that Magnus-Levy's arguments to the contrary are but little convincing. Finally, for the possible assumption that the Bence Jones' substance originates during the process of gastric or intestinal digestion there is at present no basis.

Paratyphoid Infections.—Warren Coleman and B. H. Buxton analyze the symptoms of typhoid fever as follows: In view of the care with which the cases from whose blood the paratyphoid bacilli have been isolated were studied, it must be admitted that these organisms are capable of causing a general infection that has to be reckoned with in the diagnosis of typhoid fever. An analysis of the symptoms of the reported cases demonstrates that this infection closely resembles true typhoid infection, and may even be identical with it in clinical manifestations. Practically all of the cases of paratyphoid infection passed clinically for typhoid fever, without a Widal reaction, until careful bacteriological examination revealed their true nature. Apparently paratyphoid infections may be mild or severe as in genuine typhoid. The symptoms of invasion are practically the same. Moreover, during the course of paratyphoid infection the patient develops the typhoid state, slight or profound, accompanied by the typical symptoms of typhoid fever, even quite a typical temperature curve. The pulse is that of typhoid fever. The urine sometimes gives the diazo-reaction. Typical complications have been reported. Even a relapse has been reported. So that the picture is more or less complete. For the most part the cases have been mild, and the prognosis seems to be favorable. The writer thinks it doubtful if the serum reaction will prove of value in distinguishing the intermediates as an entire group from typhoid on the one hand and coli communis on the other. All observers agree that they do not form gas in lactose or saccharose media. There is gas formation in glucose and maltose. Milk is not coagulated. On potato the growth is slight and there is no discoloration.

The Fluorescence of Quinine and Other Remedies Employed in Malarial Fever.—A. F. A. King says that it has been recently maintained that the malarial parasite will not sporulate in the dark; that the light it has in the blood is red; and since it has been demonstrated that amœba proteus streams in the presence of red light and ceases to stream in violet light, it has been assumed that the same may be true of the malarial amœba. The inference follows that the curative effect of quinine may be due to fluorescence, producing violet rays of light in the blood. Two other vegetable products with blue fluorescence in a high degree have long been known as effective remedies for intermittent fever, viz., esculine and fraxine. The tincture and other preparations of iodine have been successfully used in intermittent fever for a long time. Iodine is not fluorescent, still it must come in contact with starch and form blue or violet iodine of starch in the body. But to prove that quinine actually produces fluorescence in the body, and that coincidently the symptoms and phenomena of malarial fever disappear direct experiments are necessary. These results were obtained more than thirty-nine years ago, in the experiments of Rhoads and Pepper. The fluorescence of the blood of malarial patients was found to be below the normal standard. It increased with the giving of cinchona preparations and also when the symptoms of the disease improved. It is the peculiar relations of the chinchona preparations with light that suggest the explanation of their curative effect. How are the cases explained which quinine fails to cure? In these cases the febrile paroxysm is not produced by the usual tertian or quartan parasite, but by the malignant crescentic form. These parasites are not generally found in the peripheral circulation, but in the brain, spleen, bone-marrow, and liver, which are the darkest parts of the body, and where the fluorescent property of quinine is powerless. The writer believes that only such a part of any generation, the blood corpuscles of which have become large enough to get arrested in the peripheral circulation, sporulate at any one paroxysm. The others must take their turn, waiting until their particular corpuscles have sufficiently increased in size to be arrested in the skin, where sunlight will secure their sporulation also.

A Case of Aortic Insufficiency, with Pericarditis, Pleurisy, and Mediastinitis.—This case is described by Augustus A. Eshner. The patient was a printer, forty years of age. He complained that he had suffered constant pain throughout the entire chest and back for four months. It was worse at night and during inspiration. There was palpitation of the heart and some dyspnœa. The cardiac impulse was visible in the sixth interspace on the left in the nipple line. Systolic retraction of the intercostal spaces took place over a large extent of the inferior portion of the left chest, both front and back, and some degree of retraction appeared on the right side inferiorly. A thrill was palpable over the body of the heart, and apparently a separate and more marked thrill in the aortic area, and a thrill also to the right of the sternum in the third and fourth intercostal spaces. The thrill was in each instance diastolic. Auscultation revealed a rough, musical murmur, audible throughout the præcordium, but loudest in the aortic area. It could be heard at a short distance from the chest, and was to be heard in the axilla and back. This sound was followed or preceded by a dull, booming sound, synchronous with the impulse of the heart and the radial pulse. At the base of the heart creaking sounds were heard with the cardiac sounds, and fine crackling was heard when the patient's body was inclined backward. The radial pulse had a water-hammer character. The area of percussion dulness was large. It was doubtful at first whether the musical murmur was systolic or diastolic, but it was finally proved to be the latter. As to the thrill palpable in three situations with varying intensity, there was some difficulty in giving a satisfactory explanation. The creaking sounds at the base of the heart were suggestive of adhesions from previous pericarditis and pleurisy, with involvement of the mediastinal structures, and the thrill in the same situation may have been due to circulatory disturbances in an atheromatous aortic arch, possibly dilated at its origin. The thrill over the body of the heart may have had the same origin, or it may have been due to vibrations in the anterior mitral leaflet caused by the blood current sent by the aorta into the ventricle. The systolic retraction on both sides of the lower chest seemed to prove the presence of pleuro-pericardial adhesions. In this case there is a history of scarlet fever, smallpox, and influenza, which would account for the inflammation of the serous membranes, and even of synovial membranes.

The Relation of Irregular Pulse to Cardiopathic States.—Joseph M, Patton holds that in adults persistent irregularity of the pulse (not including the very pronounced forms) is not necessarily due to myocarditis, and that even intermittence developing in senile life does not perforce indicate cardiovascular degeneration, as proper diet and care in the use of tobacco, coffee, and stimulants will enable such subjects to live to a ripe old age. As to whether irregularity is a usual or an invariably accompaniment of myocarditis, the author, from his experience, answers this in the negative, as he does the question whether degrees of irregularity, if present, are indicative of extent of myocardial involvement or of the imminence of asystolism. Irregularity of the pulse has no definite indication *per se* in relation to insurance examinations, other than as a symptom demanding investigation as to its cause, particularly in respect to the presence of cardiac, cardiovascular, or nephritic lesions whose presence may be indicated by such pulse irregularity, but just as frequently is not.—*The Medical Examiner and Practitioner.*

Therapeutic Hints.

Flatulent Dyspepsia.—

℞	Aquæ chloroformi	
	Aquæ destil.	
	Aquæ menth. pip. . . . . .aa	℥ii.
M.	S.: Teaspoonful before meals.	

Inflamed Throat in Children.—

	Potass. chlor	ʒss.
	Mellis	℥ss.
	Acid carbol	gtt. iv.
	Aq. destil. . . . . .q.s. ad	℥iv.
M.	S.: gtt. xv. every half hour.	—Hoadley.

Treatment of Pneumonia.—E. D. Chesebro (*Providence Medical Journal*, March, 1902) says: "In a disease so varied in its manifestations and symptomatology, occurring as it does at all ages and among all sorts and conditions of men, it is impossible to formulate a routine method of treatment which will apply to all cases. To summarize the outline of the treatment, however, I would lay special stress upon the importance of the following procedures: (1) Place the patient under the most favorable hygienic conditions with special reference to ventilation. (2) Carefully regulate the diet, guarding against constipation, and insisting upon the liberal use of pure, cool water. (3) Early in the course of the disease employ counter irritants, particularly in the bronchopneumonia of children. (4) Relieve distressing cough by inhalations and, if necessary, by the use of opium or its derivatives. (5) Relieve pleuritic pain by the intermittent use of hot or ice poultices or by the subcutaneous use of morphia. (6) Reduce temperature, if necessary, by bathing. (7) Stimulate heart with strychnine, and in selected cases with alcohol, digitalis, and normal salt solution. It is possible that venesection, which may be followed immediately by the injection of normal salt solution, is indicated in certain cases of engorged right heart, and if boldly done may be instrumental in saving life. (8) Employ large and frequently repeated doses of antipneumococcic serum in desperate cases, particularly in those with a tendency to extension of the inflammatory process."

Dyspepsia.—

R	Resorcin resublim.	5
	Bismuth. salicylat.	10
	Natrii bicarb.	15
	Sacchari alb.	15
M.	S.: One small teaspoonful every two hours.	
		—Ewald.

Drunkenness.—

R	Chirata	℥ss.
	Boiling water	Oi.

Give one or two ounces of this infusion three times a day, and repeat when craving for drink returns.

—Hammond.

Angina Pectoris.—There are two designs in managing a case of angina pectoris, one being to overcome the immediate attack, and the other to prevent subsequent attacks, which almost surely will follow without adequate prophylactic measures. To meet the first indication, of quickly overcoming the excruciating agony that seems to threaten the very life of the patient, we know of nothing better (nor has anything superior been brought out during the past quarter of a century) than nitrite of amyl. Two or three drops inhaled from a handkerchief will, in almost every instance, very quickly relieve the distress. The one great drawback in the use of this remedy lies in the fact that its effect is of short duration, and hence in a protracted case an agent with more stability of effect will be required. Here nitroglycerine becomes of marked value. It can be given hypodermically—indeed, is best so given—and while it requires a longer time before the effect is obtained, that effect does not soon pass away, and can be maintained for a lengthened period by a reintroduction, from time to time, until the force of the paroxysm has been broken. Some aid is afforded by the application of external stimulants, as turpentine, mustard, and hot cloths, or a hot-water bottle. At times nothing short of the hypodermic use of morphia and atropia will suffice, with chloroform inhalations preceding the effect of the injected anodynes.

—*The Clinical Review*, March, 1902.

Therapeutic Suggestions.—Freckles are said to be readily removed by a lotion of equal parts lactic acid and glycerin. Lanolin will prevent bedsores if rubbed into the skin as soon as it becomes red and tender. Malt extracts, cod-liver oil, the phosphates, etc., should be given with or directly after food. Sulphuric acid lemonade should be used by painters as a prevention and cure of colica pictonum. It is said that warts may be removed by painting them once a day with a concentrated solution of bichromate of potash. Torpid ulcers, even when painful and due to varicose veins, may be made to cicatrize comfortably if dusted daily with antipyrin. For removing ink stains use a solution of chlorinated soda. Wet the stain with the solution, and wash thoroughly after a few moments. Acids, as a rule, should be given between meals; acids given before meals check the excessive secretion of the acids of the gastric juice. A carbuncle may be arrested in its development by the injection into different parts of the tumor of five drops of pure liquid carbolic acid at each point. A simple and, it is said, effective treatment for itching piles is the application once daily after defecation of a few drops of collodion on absorbent cotton. Dr. Wilson says that equal parts of glycerin and water, with sufficient lemon juice to make the mixture agreeable to taste, is an excellent mouth wash in fever cases.

Acute Pharyngeal Gout.—Lermoyex and Gasne enumerate as characteristics of this condition the following: (1) Sudden onset, acute course and instantaneous disappearance of symptoms; (2) High fever with speedy lowering of the general vitality; (3) Local pain, very intense and out of proportion to the apparent involvement of the throat; (4) A tendency of the inflammation to descend to the larynx instead of being confined to the general region of the faucial pillars; (5) The red œdematous appearance of the throat, inflammation of the pillars, thickening of the palate, elongation of the uvula and tumefaction of the posterior pharyngeal wall; (6) The absence of any exudate and (7) The constant escape of the glands at the angle of the jaw.—*Annales des Maladies de l'Oreille, etc.*

Society Reports.

AMERICAN SURGICAL ASSOCIATION.

Twenty-third Meeting, Held at Albany, N. Y., June 3, 4, *and* 5, 1902.

THE meeting, which was largely attended, convened in the Senate Chamber of the Capitol.

President's Address.—Immediately after the executive session, the President, Dr. DEFOREST WILLARD of Philadelphia, read his address. He thanked the association for the high honor which it had conferred upon him—the greatest, without doubt, in the control of the surgical profession of the country.

He felt sure that there would be more than enough of technical detail to satisfy the members, and therefore confined his remarks to a sort of retrospect partly of surgery in general, but more particularly of the early life and development of the association. From the first volume of the transactions, published twenty years ago, he read quotations which wrought smiles on every face. The charter members of the society, taken as a whole, "thanked God that they were too sensible to indulge in the freakish practise of Listerism," and deemed it the height of absurdity that micrococci caused pus. In its two decades of life the association had witnessed the absolute revolutionization of surgery, and no one needed to be prophetic to assert that twenty years hence excerpts from to-day's proceedings would sound as foreign to reason as those of the early eighties seem to us. In closing, he urged the great need of making the association exclusive, but only in the highest sense. Admission must be only after the candidate shall have shown unusual aptitude or brilliancy, but fully as important as these Dr. Willard placed individual character. The surgical section of the American Medical Association is large enough for all, and its open doors admit young and old; known and unknown. From it, to a large extent, should be drawn the young blood which is necessary to maintain the present high standard of the association. During the year the following men passed from the membership rolls: Sir William MacCormac, and Drs. E. M. Moore, Christian Fenger, Levi C. Lane and Clayton Parkhill.

Report of a Successful Case of Gunshot Wound of Stomach and Liver with Posterior Drainage.—Dr. ROSWELL PARK of Buffalo read this paper. He presented the case of a young woman, twenty-six years of age, who was shot with a small caliber pistol in the midline, just an inch above the tip of the xyphoid. He saw and operated upon her one and one-half hours after the receipt of the injury. The wound area through the parieties was excised by a double elliptical incision and the abdomen explored. The left lobe of the liver was deeply cut and the stomach perforated. There had been very free hemorrhage, and with the hand he scooped away upward of two quarts of clots and detritus. The gastric wall was closed by three sets of sutures; no bullet was found. Free drainage was established through a posterior incision, a tube projecting into the lesser omentum.

The recovery was uneventful. He called the Fellow's attention to the mode of drainage and to the fact that no effort was made to find the bullet.

The Importance of Drainage in Bullet Wounds of Intraperitoneal Viscera.—Dr. L. M. TIFFANY of Baltimore cited two intricate cases of visceral lesions by pistol bullet, both of which recovered. Inasmuch as the great majority of these wounds are infected in a part, at least, of their course, it is common sense and good surgery to drain each and every one. He aptly likened the abdominal cavity to a honey-comb, the cells being the thin and friable-walled viscera; the honey, their infectious contents. LaGarde's experiments showed most conclusively how rapidly a bullet became infected, granted that it started germ free, after the first perforation it was a lethal agent, nevertheless. A most important factor in establishing drainage was to determine from what direction it should flow. The ideal course natually, was from within *out*—this could easily be accomplished by over-filling the capillaries and arterioles with normal salt solution. To accomplish this inside-out flushing he gave intravenously during the operation 2,000 c.c. and a hot enema. For several days thereafter he injected 1,000 c.c. q. 6. h.—and gave no food or drink for a week. As soon as a good flow was established at the drain he made a favorable prognosis. The peritoneum is thus made to wash itself.

Results of Wounds of the Large Joints by Modern Military Projectiles.—Dr. C. B. NANCREDE of Ann Arbor, through an unfortunate misunderstanding of the time limit, was not able to read this paper. A portion of it was embodied in the discussion.

A Report of a Case of Gunshot Wound of the Spinal Cord.—Dr. R. H. HARTE of Philadelphia said that the literature of the subject cited many cases in which regeneration of the cord had been shown in frogs, lizards, and other lower forms, but not in the higher vertebrates. A case which had been under his care, but upon which he had not operated, had been shot almost a year and a half ago with a 32-caliber revolver, just below the seventh dorsal vertebra. The paralysis was total below the tenth dorsal spine, and three and one-half inches below the umbilicus. There was every classic symptom of total severance of the cord at the point of injury. Laminectomy was done, the bullet was found within the canal, and the cord in which was a space of *three-quarters* of an inch, juxtaposed. This technique was found to be most difficult, inasmuch as the membranes had been destroyed. The reader then told in detail the gradual but gratifying progress of the case. To-day practically all functions were restored, but the muscles were, as yet, feeble. The only really distressing fact in this remarkable case was that of a very persistent and exhausting clonus of ankle and knee. The conclusions were self-evident: We should operate in vertebral cases on precisely the same indications, and as freely as in cranial, and the earlier the better. No one could clinically differentiate concussion, contusion, or section.

In opening the discussion Dr. RODMAN of Philadelphia said that the chairman evidently remembered that he formerly lived in the land of humming bullets—Kentucky. He agreed thoroughly with Drs. Park and Tiffany as to drainage. Hæmatemesis had always been considered very characteristic of perforation of the stomach, but recent reports from South Africa showed that it could be caused by the mere impact of the bullet in the neighborhood of the stomach. Bullets, with practically few exceptions, were septic. For drainage of these cases he prefered a glass tube with gauze in it. In gastric wounds the lesser peritoneal cavity should be drained; if there was much extravasation, the irrigation should be *free*, otherwise he agreed with Dr. Tiffany in the value of the dry toilet of the cavity. As time was a very important factor in these operations, searching for the bullet was not alone useless, but fallacious; the most it could do was to form an abscess.

Dr. CARSON of St. Louis was opposed to flushing the abdomen under all conditions. He had never had a case terminate successfully. He commended the posterior in addition to the anterior drainage.

Dr. NANCREDE of Ann Arbor took exception to the teachings of most textbooks, which hold that bullet injuries to the great joints are very grave. This fictitious idea originated from the days of '61, when over 98 per cent. of such cases died. Records of over 10,000 wounds from modern warfare gave to them a mortality of between 2 per cent. and 3 per cent. A great revolution in this teaching was demanded. Due to the absence of wax and grease, the modern bullet was aseptic; the track usually a smooth, round one. Teachers should differentiate between the so-called civil bullets and those of the modern military arm. Admirable results were obtained in all the latter cases by rest, cleanliness, and passive motion.

Dr. Bell of Montreal said that he had made many experiments in higher vertebrates to determine how to approximate the cord and hold it after a segment had been removed. He had been unsuccessful, but glad to be encouraged to new effort by this remarkable case.

Dr. Montague of Troy had seen many cases of abdominal injury during the Civil War. In those days the bullets weighed an ounce, and the holes were large. Drainage was used then, and was surely indicated now.

Dr. Estes of South Bethlehem said that conical slugs deviated from their trajectory, so that the entrance wound might be much larger than the track through the viscera. For the wounds of civil life, where clothing was generally carried in, and which were, in most cases, septic, free drainage was necessary. Nine years ago he had a case similar to Dr. Harte's. Here the membranes helped him in suturing the cord. The man made good trophic improvement, but, unhappily, had to be removed from the hospital to a less favorable environment, as a result of which he died. He suggested that, in partial section, the membranes might form a very valuable aid in effecting juxtaposition.

Dr. McGraw of Detroit said that he was a young surgeon of sublime ignorance in 1862. He was put in charge of three hundred men, too badly wounded to be moved North. He followed Sherman in his march to the sea. The men had fought for two long hard years. They had not the power of resistance possessed by our soldiers of 1898. As the army forged through Georgia, the men grew progressively weaker, and the mortality rate was higher. The records of those days were absolutely worthless; there was no time to keep them. These matters must be weighed in comparing the recent with the Interstate war.

Dr. Weeks of Portland said that in cases of marked extravasation drainage was necessary; not so in the dry type. To drain, gauze should be soaked; it sufficed for serum, but not for pus.

Dr. Van der Veer of Albany saw many wounds in '61. Save in cases where the viscera protruded, none were operated on, and all were fatal in either event. Naturally, there were strange exceptions to this, which no one could explain. Injuries to the hip killed in 98 per cent. of the cases. To his great pleasure, he saw, soon after the battle of San Juan, an officer whose hip had been pierced by a Mauser. In ten days it healed. This would have been fatal in '61.

Dr. Abbe of New York said that functional restoration after union of nerves was at best rare. He would scarce expect it to take place in the cord without a resection of the vertebræ in the event of their not having been crushed by the injury. Dr. Eliot of Boston had suggested that drainage should be made from the suspected area to the nearest surface point. He formerly used tubes, but now preferred gauze, which he replaced deep in the wound by the aid of retractors.

Dr. McArthur of Chicago had admitted that in the treatment of infected knees he could not go as far as Mayo, who divided the patella to win free drainage, but he did make very free lateral incisions and passed gauze from one to the other.

Dr. Binnie of Kansas City said that the *dressings*, not drains, should be put within the joints if infection was to be avoided.

Dr. Park in closing said that Dr. Harte's case violated all laboratory and clinical ideas. He cited a very unusual case of spinal respiration in an instance in which the wound communicated with the lung.

Dr. Tiffany objected to the too free use of the posterior drain, since it might frequently perforate the diaphragm because of its obliquity. Gauze drains should, if all be well, not be changed till danger was over, especially if there were well-dilated vessels to feed them. Dr. Harte said that the character, the time and mode of reception were points of import in determining treatment. No one could say whether an abdomen was infected or not. Therefore all should be drained—preferably with gauze, which he was accustomed to leave in six or seven days.

Removal of the Prostate and Bladder through Suprapubic Incision for Carcinoma.—Dr. M. L. Harris of Chicago made this communication His first point lay in the technique. He made a cross section of the urethra at the triangular ligament and peeled the bladder up with the prostate. He was able to save a small portion of the bladder, out of which he fashioned a new but very small viscus. At the end of two months he had been astonished to find how extensively it had regenerated to form a very considerable cavity.

Anatomical and Technical Reasons Why the Perineal Is Preferable to the Suprapubic Route in Prostatic Surgery. Illustrated by Specimens.—Dr. J. E. Moore of Minneapolis said that the days of the catheter were past. Perineal prostatectomy was the operation of the future. The bladder was not the offending organ and should be let alone. The function of the prostate was generative, not urinary; those who had difficulty in urinating after suprapubic operation suffered because of bladder injury. He maintained that the distance from the prostate to the skin was twice as great above the pubes as below it. He endorsed the median operation, but said that complete excision of the prostate was not often indicated; generally the isthmus should be left. Lateral incisions if used might branch out in the form of a Y and reach down to but not through the perineal muscles.

Permanent Suprapubic Drainage in Tuberculosis of the Bladder.—Dr. Chas. A. Powers of Denver presented the history of a man who had suffered with progressive vesical tuberculosis. It resisted all local treatment, but yielded to permanent suprapubic drainage, which has now been established about five years. There had been progressive improvement in general health and freedom from vesical disturbance. Save for the annoyance of carrying the receptacle, the patient was absolutely comfortable.

Dr. Ransohoff of Cincinnati, in opening the discussion of these papers, devoted his attention to a consideration of prostatic abscess. Within the parenchyma such affections were rare—consequently they were often overlooked, and assumed a latent form of great danger. He chose the curved pre-rectal incision, which had few dangers and great advantages. It was astounding with what ease the prostate literally popped into sight if properly manipulated. He absolutely condemned the mode of incising abscesses through the rectum. There was no need of it when the gland could be so easily reached. The median incision did not compare with the curvilinear.

Dr. Eliot of Boston had found it useless to remove the middle lobe alone. The operation, to be successful, should be complete. On the whole, the perineal route was most satisfactory. Dr. Weir of New York remembered removing a large part of several bladders, and had noted the strange tendency to regeneration which had characterized Dr. Harris' case. He had also had a case like Dr. Powers'. He commended the curvilinear incision for perineal prostatic work.

Dr. Ochsner of Chicago said that only after adopting the perineal route had he become truly at home with prostatectomy. He urged the use of the curved incision.

Dr. Meyer of New York said that primary tuberculosis of the bladder was very rare. He had a case in '94 which he kept very comfortable for six years by using permanent bladder drainage.

Dr. Finney of Baltimore found it strange that no mention had been made of the Bottini operation. On the basis of Young's results, soon to be published, he felt that it would be the operation of the future. He referred to an incision over Poupart's ligament, which he has found useful in difficult cases to combine with the perineal route.

Dr. Abbe of New York noted that the important point in preventing bladder leakage after suprapubic drainage was established was to invert the mucous membrane. Eversion of this caused dribbling.

Dr. Moore, in closing, said that the growth of prostatectomy had been wonderful, and the discussion had made it clear that the question of incision in the perineum was not at all important. Some operators preferred the straight, some the curved, incision. As the men on whom the operation was to be done grow younger, as they would it would become necessary to save the seminal ducts. He thought he had effected this in a recent case.

Abdominal Hysterectomy.—Dr. J. B. Deaver of Philadelphia read this paper. Myomectomy was indicated only in the rarest cases. Supravaginal amputation was the best technique, since it preserved the anatomy of the vagina. All functions, save that of childbirth, should be retained. The vaginal route had, save in very rare instances, naught to commend it, but the advantages of the abdominal path was so obvious as to make it unnecessary to cite them.

A Case of Fatal Acetonæmia Following an Operation for Appendicitis.—Dr. G. E. Brewer of New York reported this case. Briefly, it was that of a boy, aged twelve, who was operated on forty-eight hours after the development of acute appendicitis. It was a perfectly straight and ordinary case. The cavity was drained; the temperature and all other evidence of sepsis subsided in two days. Suddenly, like a bolt from a clear sky, the child awoke from normal slumber, shrieking with evidence of the most horrible mental anguish. He then became somnolent. For three days these attacks continued, the sleeping period gradually changing into one of coma. There were no physical signs to explain this strange phenomenon, and not until the sweet odor of acetone was noted was there any suspicion as to what ailed the child. This product was found in great quantity in the urine, and, although every effort was made to eliminate it, death was seen to be certain. In the literature no mention was made of acetonæmia following operation in a case not diabetic. It seemed, however, that this was surely the cause of death, as, by exclusion, nothing else could be found. In the light of recent experiments by Herter, acetone probably killed by rendering the blood acid, and thus preventing it from taking up the carbon dioxide of the tissues.

Dr. Deaver of Philadelphia regarded this as a case of simple sepsis.

Dr. Brewer, in closing, presented the case in fuller detail, leaving absolutely no doubt as to the correctness of his interpretation, and the impossibility of sepsis having played any part in its fatal issue.

Second Day—Wednesday, June 4.

Supravaginal Hysterectomy from a Technical Standpoint.—Dr. W. G. Macdonald of Albany read this paper. He first stated that, save in a few instances, the supravaginal operation as first executed by Kimball of Lowell, Mass., was preferable to any other. We had, he said, departed from it to our great loss—the multiplication of fantastic instruments showed an era of degeneration, from which we were but just beginning to emerge. Many tumors exist without causing symptoms—these, save in cases of possible malignant degeneration, should be left alone. Particularly was the abdominal path indicated in the treatment of all cases where there had been previous abscess formation and rupture into or incision through the bladder, vagina, or rectum. There were but four matters of interest in connection with the operation of hysterectomy—the uterine and ovarian arteries; the round ligaments and the ureters. Kelley's method of splitting the uterus, while admirable in many ways, had certain limitations. He showed numerous sketches which detailed his slight modification of this operation, which, in his opinion, so far improved it as to make it feasible in almost every case. There were types of fibroids—those which were incarcerated in the pelvis—which no corkscrew will pull out, to which it was peculiarly applicable.

Myomectomy vs. Hysterectomy.—Dr. A. J. McCosh of New York presented this communication. Gynecology, he said, had been the last of all departments of surgery to become conservative. The time was surely ripe that some definite action be taken in this department, directed toward a preservation of one of the most precious systems of organs in the human body. Six years ago, in his private and hospital practice, his proportion of myomectomies to hysterectomies stood about one to five. This gradually decreased, till last year they were about even, and now the proportion of the preservative operation was fully double that of the destructive. There were no fibroids, save those which endanger life, which will not yield to myomectomy—neither position, nor size, nor number of the tumors have any very great bearing on prognosis. He had removed fibroids weighing ten pounds and more, and had enucleated from a single uterus more than twenty small tumors. The technique depended entirely upon free incision both of the wall of the uterus, which was split from fundus to neck, and of the tumor capsules and upon rapid and fearless divulsion of the growths. This was all that was necessary to avoid hemorrhage, which in his last forty-seven cases had caused no trouble. Naturally, after so severe an ordeal, the organ was left in a ragged and, apparently, hopeless state, but if trimmed, juxtaposed and sutured, nature would do much to remould it to normal shape. The horns and canal if possible should be preserved. These cases ran a temperature for a few days, about a degree higher than hysterectomy, it might be from slight sepsis due to the splitting of the uterus—may be from shock. He had followed thirty-two of these cases and twenty-seven have had practically normal menstruation. Of the thirty-two three had become pregnant—a condition absolutely impossible prior to operation.

The Choice between the Suprapubic and Infrapubic Method, of Reaching Tumors and Other Surgical Lesions of the Pelvic Organs.—Dr. Maurice H. Richardson of Boston read this paper. He said that what he had to communicate was based on about 260 supravaginal operations as opposed to six which he had performed through that strait. It might therefore, and with a considerable degree of justice, be criticised on the ground that his experience had been one-sided. There were four guiding rules to consult when trying to choose between the two paths—pathology, anatomy, feasibility and experience. The third must, indeed, be great to cause one to assume the risks incident to a vaginal operation.

Abdominal Route for Approaching Rectal Tumors.—Robert Abbe of New York read this paper. He called attention to the fact that clustering around the main problem are many minor questions which are in themselves of profound importance. Some of them, as, for example, colostomy, touched on the preparation of patient and area before the operation, others, as the character of the incision and the ligation of the internal iliacs bore on its immediate execution. He gave, in detail, the anatomy of the rectum, and stated that two-thirds of all malignant tumors were below the attachment of the peritoneum. He had striven a long time to devise some more laudable path of reaching the peritoneum than the simple but inadequate perineal or the cumbersome and difficult Kraske. While this latter operation was most admirable for certain conditions, there was the ever-present danger that we might not cut the upper segment far enough away from the growth, through fear that we should not be able to carry it down and unite it to the anal remnant. Furthermore, there was the danger in each of these lower operations that we might tear too many of the hemorrhoidal veins in our efforts to free the upper fragment, and this might result in the death of the part. He consequently urged very strongly the adoption of the abdominal plus the sacral or perineal route. At the time of operation permanent vaginal colostomy should be established. Choosing a point well above the growth and working through a free adbominal wound, a purse string suture was cast about the gut—a similar one was placed below—each was tied off and the gut divided. This technique gave an absolutely free and clean operative area. Each end was invaginated and permanently closed. This suprapubic opening gave just the same chance for manual and visual examination of glands and other structures in operating on the male rectum as it did in the like technique for hysterectomy.

Dr. **Eliot** of Boston opened the discussion. The fact that he had had but two deaths in a recent series of seventy-four consecutive hysterectomies seemed to justify the incursion of the general surgeon into a specialty. Splitting the uterus prior to its removal had the danger that germs might be spread from its foul interior. This would naturally be equally true in the radical form of myomectomy advocated by Dr. McCosh. This, however, was a coming operation, for altogether too many precious organs had already been sacrificed. Though not untrained as a gynecologist, he found the vaginal route unsafe. Some years ago he operated vaginally on five cases, and immediately afterward did a laparotomy. In every single case he discovered a more or less grave point of faulty technique.

Dr. **Allen** of Cleveland said that the condemnation of the vaginal route had been too sweeping. There was room for much good and swift surgery through that path, and so far as vision was concerned, no technique afforded so clear and perfect a view of the roof of the vagina and of the cervix as the vaginal. Particularly was this route indicated in operations not complicated by uterine adhesions, and in the radical treatment of sudden and severe and uncontrollable uterine hemorrhage. We should not ignore the lower route.

Dr. **Vander Veer** of Albany had done all forms of operations on the uterus. He had a great collection of varied instruments which had come and gone, and the world was better for their going. He feared that if the uterus were bisected in a great number of cases, we should, sooner or later, have serious septic results. Pathology was the keynote to success in surgery.

Dr. **Mayo** of Rochester, Minn., spoke in favor of conservative surgery for non-malignant cases. His experience with this type of disease, save where it had attacked the uterine body, had been most gloomy. When Reese and Clark explained the reasons for the removal of the lumbar glands, he practised it hopefully and freely, but with no success. Great care should be taken to guard against infecting with cancer the raw regions of the operation ground. The old rule that incisions to free the patient from a malignant growth should be 4 cm. from it, could stand in cases of carcinoma of the cervix. Hence, probably, the bad results. He agreed with Dr. Abbe in that Kraske's operation was bloody and incomplete, and that its value was much enhanced by adding the suprapubic incision.

Dr. **Carson** of St. Louis recommended an anterior colpotomy; through it, after separation of the bladder from the uterus, a most excellent view can be had of the uterus and appendages.

Dr. **Eliott** of New York said that the reason for the gloomy outlook which was so universal and so true in cases of uterine carcinoma, arose largely from the fact that they were seen so late. Although the growth might appear on primary examination to be localized, there was almost no doubt, reasoning both from analogy with other cases of malignancy, and from the subsequent history of uterine carcinomata, that the glands draining this area were always involved. The supravaginal route was, therefore, always to be preferred.

Dr. **Harris** of Chicago stated that he had been in the habit of operating in certain cases in two stages—first, by the abdomen, then by the vagina. This was specially indicated when there existed a septic discharge in a case not suitable to vaginal hysterectomy. He favored preliminary colostomy in all cases of rectal carcinoma, and pointed out that the vagina was a useful route for operating on such cases in the female. He had recently removed eight inches of great gut in this way.

Dr. **McArthur** of Chicago had had a most remarkable case. Necessity had compelled him to provide her with two anal openings, one in the vagina and one near the normal site, each of which she successfully used at different times. Inasmuch as these operations were, at best, palliative, the opening should be made where it was least annoying to the patient.

Dr. McDonald, in closing, said that it was very evident, from the trend of the morning's discussion, that the general surgeon was, very properly, coming into his heritage. He strenuously defended the technique of splitting the uterus, which might extend transversely or longitudinally. There would be a somewhat higher mortality following myomectomy than hysterectomy, but because of its vast advantages it was the coming operation.

Dr. McCosh said that if cancerous involvement of the broad ligament glands had taken place, the case was hopeless. Therefore, it followed that very many hysterectomies for malignancy should be done vaginally. He emphasized that he had not been forgetful of the danger of sepsis attendant on splitting the uterus, and had consequently had smear cultures made in twenty-nine recent cases. One only had been found to contain pyogenic organisms.

Dr. Richardson expressed surprise that there was anyone present who would even countenance vaginal hysterectomy. He had supposed that even his weak praise would have been too strong for most of the Fellows.

Demonstration of a Method of Intestinal Anastomosis.—Dr. O. H. **Allis** of Philadelphia gave this demonstration. He first showed some very dainty tenaculum forceps, four of which were used in his technique. It consisted in a through-and-through stitch, which strongly effected the union in the cloth gut, used for demonstration.

The Teaching of Surgery, with Special Reference to the Didactic Method.—Dr. J. D. **Bryant** of New York presented this paper. Disease and health each had a language. They were analagous, but not homologous. That of disease was called the signs and symptoms. Medical interpretation of a case as fully was important as good surgical technique. The language of each was distinct, but similar. He gave the synopsis, which he had used for many years in teaching surgery: (1) Definition; (2) Anatomy; (3) Pathology; (4) Causation; (5) Symptoms and Signs; (6) Diagnosis; (7) Complications; (8) Treatment; (9) Prognosis; (10) Sequelæ.

Clinical teaching alone unfitted the student to practice; this was equally true of didactic teaching alone. There must be an even distribution of each.

The Teaching of Surgery.—Dr. H. L. **Burrell** of Boston presented this monographic dissertation. To compile it he had written to every medical school in the world, and had allotted the subdivisions of it to various Fellows for discussion. He said there was a great and inspiring progress being made in the teaching of surgery in this country. It was a topic too broad to permit of dogmatic laws; the individual must largely choose his own method of teaching. Success depended on the individual teacher; students differed very widely, some learning by sight, some by ear, some by touch. There was no universally best method. Unquestionably, there should be extra-mural teaching. A new era of surgical teaching was before us. If we fostered our opportunities and material, and added a truly scientific strain to the work, American surgery would defy the world.

Dr. **Matas** of New Orleans had been asked to speak on didactic lectures. They were bound to remain, they could not be done away with. Presenting, as they did, a sort of panoramic view of the subject to the student whose mind was filled with detail by his clinical courses, they were of inestimable worth. In Tulane University there is in force a very carefully graded system of teaching. In the first year there were classes in minor surgery; in the second, in physiologic surgery; in the third, in surgical pathology; in the fourth, regional surgery was given. All courses was compulsory; the didactic course occurred only in the third year.

Dr. Eliott of New York spoke on recitations. Surgery was naturally divided into the practical and the theoretical. The recitation system was absolutely necessary, both when the head of the department gave a topic in all detail, and when he merely touched on leading points. Honest, straightforward conferences were to be encouraged; the student should be made free to confess his lack of knowledge, and not to hide it. Personal contact with the men was absolutely essential to success.

Dr. Richardson of Boston discussed anatomy. Surgical anatomy, he said, should be taught by surgeons. They alone could be in a position to sift the useful details from the great mass which no one could retain. Such a man very properly valued the relations about the foramen of Winslow far more than the ancient but classic description of the triangles of the neck. This course should be compulsory.

Dr. Da Costa of Philadelphia spoke on surgical technique. The classic modes of applying bandages and other surgical devices had, in a measure, been put aside. The introduction of the gauze bandage was largely responsible for this. It had a very important function, but it was not useful in many of the sites where it was used. Living models must be used.

Dr. Moore of Minneapolis spoke on physical diagnosis. We examined the bodies of babies and of children nude; why deny this privilege to the adult? The student should be taught the normal variations in the extremities, and a comparison of the two sides should be insisted on. The anatomical marks and their importance should be known by everyone..

Dr. Geo. E. Brewer of New York spoke of the form of section teaching employed by him at the College of Physicians and Surgeons. It amounted to a seminar and was based on the consultation method. The essential was that the student did all the work, and its greatest advantage was that it taught him the method of exact diagnosis.

Dr. R. F. Weir of New York spoke on Clinical Instruction. It had too free a sway in New York. Next year instead of one didactic lecture per week there would be at least two. One reason for making the change was that among the better student body there was a feeling in favor of more lectures. In future Columbia would not adhere to her old and perhaps justly criticised method of teaching physiology and descriptive anatomy. Parts of these less valuable courses would be excluded to make room for the new.

Dr. Bell of Montreal said that the faculty of McGill felt most strongly the wisdom of tutorial teaching. In the hospital of the college the house surgeon exerted such control over the senior students. When he happened to be a good teacher the plan was admirable; occasionally it failed, but on the whole, it seemed to work well.

Dr. Finney of Baltimore said that at the Johns Hopkins the students did not see a case till after two years of training. All operations in the third year were done by the students on dogs. Living wounds differed absolutely from dead.

Dr. Nancrede of Ann Arbor said *all* the work which was under discussion was compulsory in his department. Much work was done in a specially appointed laboratory on the higher vertebrates. Should his dog die the student was held responsible. Post-mortems were done and effort was made in every way to run the animal operative course very closely along the lines of a hospital. The discussion had shown him that all good schools are teaching the same matter and the outlook was bright for great progress.

Dr. Ochsner of Chicago said that before proper instruction could be given the medical school must have control of its hospital. Contact of student and patient long continued he deemed necessary to success. Hence such hospitals should have many small wards—not more than six beds in each.

The Essentials of Modern Hospital Construction.—The association adjourned to the new Albany hospital where, after inspection of the beautiful broad pavilions and other accessories to a magnificently equipped institution, Dr. Van der Veer of Albany read a paper with this title. Taking the new institution as a model he described it in detail. It had cost $292,000, exclusive of the seven acres, magnificently situated on the summit of a hill at some distance from the center, which was given to the hospital by the city. Every effort had been made to make the patients comfortable—there was a guest room, even, for those whose friends were passing away. Members of the staff gave interesting demonstrations of various forms of hospital technique and, in closing, Dr. Macdonald showed a case of spleenectomy and cholecystotomy and Dr. Van der Veer one of gastrectomy of four months' duration which had so far given a most brilliant result.

Third Day, Thursday, June 5, 1902.

Complications Following Gastroenterostomy.—Dr. W. J. Mayo of Rochester, Minn., presented this paper. He had done one hundred and seven gastroenterostomies in the past ten years with ten deaths. The causes of these deaths were as follows: three from exhaustion; exhaustion with pernicious vomiting was fatal in one case; progressive pneumonia killed three, and in two cases the cause of death was a separation of the anastomosed intestine from the stomach. The great secret of how to control the pernicious vomiting was at last answered. It did not consist in twisting the gut or in doing enteroanastomosis, but in placing the opening at the most dependent portion of the stomach. Whether it be done anteriorly or posteriorly made but little difference. Enteroanastomosis was more apt to be necessary after suture than after the use of the button, but this had the very marked disadvantage that whether inserted in front or behind it might drop into the stomach. Much had been said about the contraction of the anastomotic orifice. Whether this took place or not depended absolutely upon the state of the pylorus. If it were permanently closed, it would not contract; if not, it would. One factor which very frequently led the operator into subsequent trouble was the fact that if he should have operated for the relief of an ulcer situated near the pylorus, and the rest which his efforts had given the lesion had healed it, the inflammatory exudate which at the time of operation completely blocked the pylorus would gradually disappear, and ere the opening was great enough to care for all the stomach contents the anastomotic orifice might contract and vomiting ensue. He prefered the posterior operation—not because it was easier—for it was not; not because it was posterior, but because in doing it one unconsciously but very certainly *must* open the stomach at the most dependent point. In a vast majority of cases this would prevent vomiting. If, however, it should occur secondary enteroanastomosis was indicated. For this purpose fourteen to sixteen inches of jejunum must be left in the anterior technique and ten inches in the posterior.

Dr. M. H. Richardson of Boston opened the discussion. He very freely confessed that his success with gastroenterostomy had not been great. Most of them had been moribund or nearly so at the time of operation. In any event he preferred to restore the canal at the pylorus if it were possible. That vomiting might not be due to anatomical distortion or failure was very clearly demonstrated to him recently in a case upon which he had performed gastroenterostomy and had been obliged to do pyloroplasty some months later. The healing had been perfect; there was no spur; the anastomotic opening had not contracted. For every form of obstruction he did a partial pylorectomy which was not difficult of execution and which reestablished the natural opening.

Pyloroplasty with Report of a New Method.—Dr. J. M. T. Finney of Baltimore read this paper. He first gave the history of plastic work on the stomach since its inception in 1886 and then illustrated his operation by diagrams. It might be called pyloduodenostomy and surely seemed simple enough. He first freed the pylorus and neighboring portion of the alimentary canal from all adhesions, then placed a single row of sutures of the Halstead type posteriorly, between the two organs. The anterior row was then put in and a free inverted U-shaped incision was made within a distance of about two and one-half inches between the uprights. The posterior row was tied before this incision was made, then the anterior and a few Lembert stitches were taken at the very base to make sure of juxtaposition. This procedure gave a pyloric opening of 2½ inches in diameter. This operation did away with numerous objections to pyloroplastic work.

Dr. Bevan of Chicago had done twenty cases. Death had been caused in a small percentage: one by drowning—the patient's stomach was not properly washed out and he vomited during anæsthesia; in others by pneumonia, perforation, exhaustion. He preferred the suture to the button, inasmuch as it could be done in fifteen minutes, and was so very much freer from danger. In 25 to 50 per cent. of cases of gastroenterostomy the button fell into the stomach. He found Finney's operation very cumbersome, Kocher's pylorectomy was not more complex and met more indications. He warmly criticised the use of the interrupted suture in gut work—the continuous was endorsed by the leading European workers—it gave a more even tension and was more quickly inserted.

Dr. Meyer of New York in his last thirty cases had made use of all technics, and had never had the misfortune to have a case suffer from the dreaded vomiting. The posterior was to him the natural anatomical one; even a short transverse mesocolon did not contraindicate its execution. The anterior was easier to the surgeon but the button was in this case much more apt to drop in. But not having had the vomiting was mere luck, and he always guarded against it by leaving twelve to fourteen inches of jejunum above the anastomosis, so as to have sufficient gut to make an enteroanastomosis if necessary. McGraw's elastic ligature, he was sure, was a most admirable device.

Dr. Harris of Chicago said that there was a developmental reason for the posterior being the operation of choice. When the gastric tube began to become sac-like, the posterior wall grew much faster than the anterior. It might thus happen that the posterior wall would be twice perforated by a bullet or stab wound from in front.

Dr. Van der Veer of Albany considered Dr. Mayo's paper a most valuable contribution to gastric surgery. He had used the button, and usually had operated posteriorly. Nevertheless, he agreed with Dr. Richardson that, if possible to accomplish it, there was a great advantage in freeing the normal path of obstruction by some form of pylorectomy.

Dr. Kammerer of New York had used the posterior operation, with the button, in his last thirty cases; the results of this technique were so very much more favorable that he had now abandoned the anterior route. He disagreed with Dr. Bevan in his sweeping condemnation of the interrupted suture in intestinal work.

Dr. Weir of New York, in his recent thirty cases, found that there was no use of throwing a twist in the gut, nor of making a primary enteroanastomosis. Also, the technique of suturing the gut to the stomach quite apart from the anastomotic opening, and for the purpose of preventing contraction, was of no avail. Since draining the stomach from the most dependent part, he has had no "vicious circle." He used a continuous suture. He had always been fearful that, in being over-careful in the application of rows of sutures, one might defeat the purpose for which he strove, and kill the juxtaposing surfaces by obliterating the blood supply.

Dr. McGraw of Detroit said that gravity was probably the smallest factor to consider in seeking the cause of the vomiting "circle." The difference between the peristaltic power of gut and stomach had always seemed to him to be a very potent factor. Naturally, the stomach of cases demanding gastroenterostomy was in a much weaker state than the gut below it. He urged the trial of his elastic ligature. There was no danger of its failing to cut through, provided a stout elastic be used and under good tension.

Dr. Ochsner of Chicago said that so bad were his results that, until Mayo taught him to do a gastroenterostomy six months ago, he had been hopeless of success. He now understood that it was purely a matter of drainage; with it well established, there would be no possibility of vomiting.

Dr. Rodman of Philadelphia was glad that the anterior operation could be used with good success, because there occasionally arose cases in which the posterior technique was not applicable. He said that gastroenterostomy had come to stay; this was not true of pyloroplasty. He agreed with Richardson that often a partial gastrectomy was the operation of choice.

Dr. McGraw of Detroit said that he had found the twisting of the jejunum prior to making the anastomosis was a faulty technique. It often returned to its original position, thus turning the stomach.

Dr. Mayo, in closing, said that one of the contraindications to the posterior technique was a short, fat mesentery; another was an anomalous distribution of the arterial supply. Enteroenterostomy was indicated only if the vomiting be established.

Dr. Finney said that he could not understand the apparent difficulty the members had had in comprehending his technique. It was extremely simple. He cited, in response to Dr. Bevan's criticism on the use of interrupted sutures in gut work, a large number of surgeons who prefer this type of stitch.

Surgical Treatment of Tubercular Peritonitis.—Dr. A. J. Ochsner of Philadelphia read this paper. He said that although statistics showed an apparent advantage for the medical treatment of tubercular peritonitis, they were deceiving. Surgery cured 50 per cent. of the otherwise hopeless cases, medicine 50 per cent. of all types. His conclusions were as follows: "(1) Medical treatment should be given for a long time, and should be persisted in if any improvement develops; (2) Early operations often recurred; (3) In the absence of progress, operate; (4) If disease be confined to an organ which can be removed without extensive denudations, do so. (5) In the presence of fluid, remove no tissue; (6) Intestinal fistulæ generally are the result of too much surgical interference; (7) During recovery from operation, medical treatment should be most carefully carried out; (8) Chronic encapsulated cases are particularly suitable to surgery; (9) Reoperate, if necessary.

Dr. Bevan of Chicago said that Dr. Feuger, whose absence must be deplored by each and all, had worked the matter out very thoroughly. He had shown the absolute futility of operating on *any* case of tubercular peritonitis. It created but a seeming recovery; the exploratory operation was useless. The two recent cases at the Presbyterian Hospital had been turned over to the internists, who had used the *x*-ray with success.

Dr. Burrill of Boston disagreed with each of the speakers. It was not easy to diagnose tuberculous peritonitis. Grossly, there is the matted type—the acute and chronic exudation.

Dr. Mayo of Rochester said that no case free from fluid was surgical. One might, however, just as well expect an ovarian cyst to disappear under medical treatment as to look to the ray or anything else, save the knife, to free the patient from the encapsulated tuberculous fluid.

Dr. Richardson of Boston said that the removal of tuberculous tissue from the abdomen had given some very brilliant results. Mere opening has undoubtedly cured very many cases.

Dr. Weir of New York said that the matted type was not surgical. He had seen the actual value of mere opening the abdomen in suitable cases too clearly demonstrated to allow him to pass an unfavorable judgment on it.

Dr. W. B. Coley of New York had studied the wonderful effects of simple abdominal section in tuberculous subjects on whom he had operated for hernia. He would continue to believe in its value.

Dr. Ochsner, in closing, said that he was happy that the section, with the exception of Dr. Bevan, supported his views. Inasmuch as the cases in which there were free adhesions were those in which the healing process was very active, they naturally were not surgical, but should be left to themselves.

Extirpation of a Leucocythemic Spleen.—Dr. T. H. McGraw of Detroit read this report. The case was that of a child, aged eight, which presented all evidence of leucocythemia, and who had had an enlarged spleen for eighteen months. There was no trouble at removal from hemorrhages, but the child died from oozing in about six hours. For this reason, and also because no important details could be gained from late removal as to the bearing of the spleen on the etiology of the disease, he urged very early operation. Transplantation of bits of this spleen into guinea-pigs had no effect.

Dr. Meyer of New York said that, in view of the utter hopelessness of medical treatment, the position of surgery to leucocythemia should be thoroughly understood, and the only way to reach any conclusions was to practice, as McGraw had well said, a number of early extirpations of the spleen.

Dr. Richardson of Boston said that his case of removal of a five-pound spleen continued well. He feared, however, that the success of this operation had been a bad example.

Cancer of the Appendix.—Dr. R. H. Harte of Philadelphia, in reporting two cases of this type, said that they were very uncommon; but seventeen had been recorded. He urged that more careful examination be made of every removed appendix.

Radical Cure of Aneurysms of the Extremities.—Dr. Rudolph Matas of New Orleans read a paper on the Radical Operation for the Cure of Aneurysms of the Extremeties, Modifications of the Old Technique, with the View of Simplifying the Classical Procedure and Reducing its dangers to a Minimum, with Illustrative Cases showing the Author's Method in Popliteal, Femoral and Brachial Aneurysms as Operated in his Clinics, and exhibited this new technique. He gave in detail the history of the many classical operations and then described his own. It consisted of a simple splitting of the sac, eversion of the clot and intrasaccular ligation of all vessels supplying it. The steps were as follows: "(1) Constriction by Esmarck or by digital pressure; (2) free incision of the sac; (3) Obliteration of all openings by purse string sutures; (4) Inversion of sac walls and tacking over them of skin, the technique gives a depression where formerly there existed a tumor. The advantages are particularly that the intervention is all from the inside so that no injury can be done to surrounding structures and that healing should be complete in a week."

Dr. Gerster of New York welcomed this interesting operation because it made the dissection of the sac necessary.

Dr. Elliott of New York said that the technique of Matas would be most valuable in the lower extremity where the anastomosis are not so free as in the upper. He feared, however, that, save in traumatic aneurysms, there might be danger of the stitches tearing out.

Dr. Matas, in closing, said that while his operation might not cover all types of aneurism, it was he thought, safer as a whole for the majority.

The Influence of the Röntgen Ray upon the Different Varieties of Sarcoma.—Dr. W. B. Coley of New York read this paper. The ray has been used but little on this form of malignant growth. He had had ten cases recently, in all of which there had been very marked improvement. Some do well if the toxines was added to the ray treatment. Although it might be true that we could not as yet cure sarcomata, when one recollected that a majority of them occur in inoperable sites it was at least gratifying that we had in the ray an agent of great inhibitive power.

Dr. Richardson of Boston had sent many cases to Dr Coley which had seemed absolutely hopeless. Some had been cured; all helped.

Dr. Gerster of New York said that it should not be forgotten that the old German surgeons got as good results with their ancient forms of treatment as we obtain to-day. He had, as yet, seen no cures—the reported cures were very possibly cases of syphilitic deposits.

Dr. Coley, in closing, said that there would seem to the fair minded to be something more than coincidence in the relation between cause and effect in his series of ten cases. These cases had been pronounced sarcomatous by the best pathologists of the land.

Cysts in Connection with the Teeth.—Dr. J. C. Oliver of Cincinnati showed a series of microphotographs illustrating the condition. The cases were usually under thirty years of age and the third lower molars usually are involved. The cause was unknown; it might be due to misplaced dental germ; to dermoidal remains, to failure in evolution. Since the cysts contain cells which greatly resembled sarcoma cells, they had often been excised and a large deforming operation done. Hence great care should be exercised in establishing the true diagnosis.

Implantation of Silver Filigree for the Closure of Large Hernial Apertures.—Willy Meyer of New York read this paper. He showed the plates which he had used with admirable success. They had square meshes about an eighth of an inch on a side and served as little nests for fatty particles to grow into. The use of these plates do not need to be limited to hernial openings, but served a useful purpose after removal of parietal malignant growths.

Report of Two Cases of Exophthalmic Goiter Treated by Operation.—Dr. Emmet Rixford of San Francisco said that only those cases in which the cardiac lesions not far advanced should be operated upon, and in all it should be done during quiescent periods. As the anesthetic was the great source of danger, many in doing the partial thyroidectomy, which was becoming the operation of choice, use cocaine. Jonnescos operation was not looked on with favor here. The immediate results of thyroid hemisection were to aggravate the symptoms for the first few days, but it cured about three-quarters of all cases.

An Improved Instrument.—Dr. S. H. Weeks of Portland showed a male sound, with filiform bougie attached, which he thought should be put into the hands of the general practitioner.

The Present Status of the X-Ray as a Means of Diagnosis and as a Therapeutic Agent.—Dr. A. D. Bevan of Chicago showed a very beautiful series of photographs, and quoted some remarkable figures obtained from the use of the ray. He said that every hospital should have a ray expert. Burns were almost certain to occur and a good operator is not responsible for them. No good results were to be had in deep-seated carcinomata, but the superficial type in which the skin had been broken often responded to the ray as if by magic. There was very great danger however, that the lay public would get the idea that in the ray they had an agent which would deliver them from the knife. This would do infinitely more harm than the ray could possible do good.

Dr. Meyer of New York said that he fully agreed. The ray was of use only in the most superficial type of carcinoma.

The following officers were elected for 1903: *President*, Dr. M. H. Richardson; *Vice-Presidents*, Drs. M. B. Carson and W. J. Mayo; *Secretary*, Dr. D. P. Allen; *Treasurer*, Dr. G. R. Fowler; *Recorder*, Dr. R. H. Harte.

The next meeting place will be Washington, D. C.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held June 5, 1902.

John E. Weeks, M.D., in the Chair.

Contagious Ophthalmia in Industrial, Residential and Public Schools, and in Asylums and Hospitals.—Dr. Richard H. Derby read this paper. (See page 10).

Modern Methods Employed in the Prevention and Treatment of Trachoma and Other Forms of Contagious Ophthalmia.—Dr. Carl Koller read this paper. The most important representatives of contagious ophthalmia are gonorrhœal ophthalmia of the adult, of the new-born, diphtheritic conjunctivitis and trachoma.

Gonorrhœal Ophthalmia of the Adult.—The stage of incubation may last from a few hours to three days. In cases of supposed infection with ophthalmia the early instillation of a 2 per cent. nitrate of silver solution into the conjunctival sac will surely prevent an outbreak of the inflammation; but such a procedure is useless, and may be harmful, if symptoms have already shown themselves prior to such instillation. After gonorrhœal ophthalmia has been diagnosed the patient should be isolated in a well-ventilated room and put to bed. The room should be darkened. The doctors and nurses should be provided with protecting spectacles. In case but one eye has been infected the other eye must be protected by a bandage; rubber adhesive plaster, not being permeable for moisture, makes the best outer covering. A watch-glass, or mica-plate, may be fastened over the eye to enable the patient to see. The unaffected eye should be so protected until all discharge from the infected eye has ceased. Such protective bandage should be changed every three or four days. On the first or second day, if the symptoms are of moderate severity, cold should be applied to the affected eye in the form of pads of cotton which have been previously saturated with a solution of boric acid or liquor Burrowi diluted 1 to 10, which are cooled on a cake of ice. Frequent changes should be made, in order to lower the temperature of the lids. These applications should be applied intermittently in order to prevent paralysis of the blood-vessels and stasis. The eye should be kept cleansed of its discharges. Kalt of Paris introduced his grands, lavages, *i.e.* the irrigations of the conjunctival sac with large quantities of a 1 to 5,000 solution of permanganate of potassium; instead of this a solution of 1 to 2,000 formalin, or of bichloride of mercury 1: 5 to 10,000 can be used. The solution used should first be warmed, and the pressure should not be greater than that obtained from a height between one and one and a half feet, just sufficient to dislodge and wash away all particles of discharge lodged in the folds of the conjunctiva. These irrigations should be employed every two hours day and night. Infected dressings should be thrown into a slop-jar filled with 5 per cent. carbolic acid solution, or 1 to 1,000 sublimate solution, or plain water. The contagious discharge loses its power of infecting if diluted with water in the proportion of 1 to 100. If cold applications are not well sustained they should be discontinued and hot applications made; these are especially useful where there is hard infiltration of the lids with tension. These hot applications should be employed for one-half to one hour at a time, with intervals of one and a half to two hours. If the swelling and chemosis become excessive, the outer canthus may be incised, which affords great relief by lessening the tension and by bleeding. While the lids are hard, especially when there are grey patches of exudation on the inside of the lids, cauterization with nitrate of silver is not advisable and may even be harmful, as it gives rise to a recurrence of the infiltration. It should not be used before the stage of pyorrhœa, in which the lids are soft, the conjunctiva velvety and the discharge creamy and very abundant. Then the lids should be everted and carefully brushed with a 2 per cent. nitrate of silver solution, once or twice a day, but not before the eschara of the previous application has been thrown off. Nitrate of silver is the sovereign remedy in gonorrhœaic ophthalmia. Protargol, and allied organic silver compounds, do not coagulate, and the coagulating power is the chief factor of its efficiency. Nitrate of silver not only has a strong bactericidal power, but it necrotizes the superficial layers of the epithelium in which the germs are lodged. The copious irrigations should be continued day and night. The stage of pyorrhœa lasts from one to two weeks. Within four to six weeks the eye returns slowly to its normal condition, although for a long time there remains some chronic inflammation and thickening of the conjunctiva over the lids and folds. A dreaded complication of gonorrhœal conjunctivitis is ulceration and necrosis of the cornea with its consequences. When it occurs in the first stage it is of sinister import. During the stage of pyorrhœa it is not quite so dangerous. Ulcers of the cornea, with their sequels, as prolapse of the iris, should be treated according to general principles, with the sole exception that bandaging the eye should never be done, on account of blocking up discharges. Prolapse of the iris should not be cut off as long as there is danger of infection, for it has been known to be followed by panophthalmitis.

Gonorrhœic Ophthalmia of the New-Born.—Irrigations of the vagina with antiseptic solutions before confinement has not much effect in preventing infection of the new born. Credé's method, introduced in 1879 in his obstetric clinic, reduced his cases from 10 per cent. to 0.1 or 2 per cent., and was a great triumph in preventive medicine. If generally used, ophthalmia of the new-born would be entirely abolished. Ophthalmia of the new-born shows itself, with similar symptoms as in the adult, usually on the third day, sometimes up to the fifth day; graver cases may appear on the first day. It is generally conceded that if the child comes under treatment with the cornea intact the eyes can be saved with certainty. An exception are cases with malnutrition and failing health. Nitrate of silver in 2 per cent. solution should be applied at once. The lids should be well everted, so that the fold of the fornix becomes movable, when they should be brushed with the solution until they become white. This should be done daily. Every half hour the lids should be separated and the discharge washed away with a cotton swab saturated with boric acid. If it is deemed necessary to apply cold, ice should not be used locally, but simply cold cotton pads should be applied. Kalt irrigates the eyes two or three times a day with a 1 to 5,000 permanganate solution, using about one quart each time, with very good results. Treatment with nitrate of silver and simple rinsing away of the discharge insures good results, and this is better in the hands of the lay people than the irrigator.

Diphtheritic Conjunctivitis, rare in this country but more common in Northern Germany, is divided into two forms, the lighter croupous and the severe diphtheritic, the difference being clinical rather than etiological. Both may be caused by the Klebs-Loeffler bacillus, but also by the streptococcus, gonococcus and other germs. Children between the ages of two and eight years are usually affected, and frequently they will be found to be suffering from diphtheritic throat and nose affections. This is one of the severest forms of ophthalmia, and the swelling and hardness of the lids reaches the highest degree and, in severe cases, the cornea is mostly lost without hope. As a rule, but one eye is first affected. If the case is severe, the antitoxin should be used without waiting for cultures. Strict isolation of the patient should be enforced. Hot applications should be made to promote circulation and resolution of the exudate. Remove the discharge as often as it accumulates. After five days the infiltration lessens, the lids become soft, and then the nitrate of silver should be employed very cautiously, using a 1 per cent. solution; this should be stopped if infiltration or membranes appear. Vaselin may be introduced into the conjunctival sac to prevent synblepharon in cases where the exudate has been thrown off, leaving raw surfaces. Corneal ulcers should be treated on general principles. Prolapse of the iris should not be cut off as long as the danger of infecting the wound exists, as these wounds become infiltrated.

Trachoma.—Prophylaxis could do a great deal toward preventing the spread of this trouble, and every physician should enlighten his patients as to its contagious nature, and should explain to them its gravity and instruct them how to prevent infection. No other person should share the bed, towel or washing utensils with an individual suffering from trachoma. Surgical measures are to be preferred but nitrate of silver and sulphate of copper should be trusted, the former for cases with moderate inflammation and with discharge, the latter for the cases of chronic infiltration. Cases of acute trachoma should be treated with cold applications and irrigations; cauterization with nitrate of silver, as a rule, is not advisable, but scarification brings relief. In the treatment of trachoma surgical methods prevail at present. Expression with roller or other forceps is now in almost universal use, and is well fitted for fresh cases with plenty of follicles and a conjunctiva which is not atrophic. Expression should be done under a general anæsthesia, after which a ½ per cent. solution of nitrate of silver is applied to every part of the conjunctiva. The œdematous swelling may be prevented by applying a bandage and keeping it on over night. Since the expression does not remove the small follicles imbedded in the conjunctiva, treatment should be continued for some time after the operation until the conjunctiva is entirely smooth. A 2 per cent. solution of sulphate of copper, in glycerin pure or diluted with water, and used for four or six weeks, will perfect the entire removal of follicles and papules. In cases where atrophy and cicatrization of the conjunctiva exist with simultaneous presence of follicles one may express the follicles between the nails of the two thumbs, which is less injurious than the forceps and a much more efficient procedure than waiting for the follicles to be absorbed. The presence of pannus is no contraindication to expression, nor does the pannus require special treatment. Where pannus exists and no follicles in the conjunctiva are present, which never happens in a fresh case, but frequently in old cases of many relapses, cutting of the blood vessels at the edge of the cornea with a sharp knife will cause the pannus to quickly disappear. In old cases of acute inflammation, whether the conjunctiva is hypertrophic or atrophic, liberal scarification of the conjunctiva will be found useful. If for all cases of trachoma a universal remedy ought to be selected which is certainly impossible, the nearest approach to it would be a solution of copper sulphate in glycerin used as eye-drops two or three times a day.

The Laws of the State of New York Relating to Contagious Ophthalmia: The Results of Their Enactment and the Desirability of Further Legislation.—Dr. Frank Van Fleet read this paper. He said that only two laws relating to contagious eye disease had been enacted in this State; one provided for the appointment of a physician to institutions caring for children; all children should be examined especially with reference to diseases of the eyes and skin, and a monthly report made. The second law related to ophthalmia neonatorum when occurring in the hands of midwives or nurses, requiring that, when noted, they should be reported within six hours. The chief source of contagious eye disease was in the public schools and public baths. Dr. Lucien Howe of Buffalo had asked for a law making the application of the Credé method compulsory; this had not met with the universal approval of all physicians. He believed that all laws relating to public health should be entrusted with the Board of Health, and that the Board of Health should work in harmony with the medical professions.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK

Stated Meeting, Held May 26, 1902.

Frank Van Fleet, M.D., President.

Medical Etiquette at the Dispensary.—Dr. Thomas J Hillis read this paper, which was discussed by Dr. Thomas H. Manley.

Gas Leakage and the Public Health.—James C. Bayles, M.E., Ph.D., read this paper, in which he stated that gas companies discussed the question of gas leakage behind closed doors, for the reason that they feared a public panic would result if more was known on this subject. The facts that he would present would surprise many who heard them for the first time. What he had to present was learned from personal experience or else was based upon technical authorities.

Composition.—He considered two varieties of illuminating gas: (1) Coal-gas, and (2) Water-gas. Coal-gas was obtained by destruction in retorts of coal which was rich in volatile hydrocarbons. The following composition of a coal-gas was typical: Hydrogen, 47.49; marsh-gas, 38; carbon monoxid, 6.74; the remainder consisted of olifient gas, carbon dioxid and nitrogen. Water-gas consisted of decomposing superheated steam to which naphtha-gas is added to give it more illuminating power; its composition is about as follows: Hydrogen, 30; carbon monoxid, 30; marsh-gas, 19.1; olifient gas, 10.65; the remainder, a small percentage of carbon dioxid, nitrogen and oxygen. Uncarburetted water-gas was a deadly gas, explosive, odorless, an energetic blood-poison. Carburetted water-gas was only less dangerous than the blue-gas because of its offensive and characteristic odor, which allows its presence to become known. It is equally as dangerous as the uncarburetted water-gas. He considered coal-gas less dangerous than water-gas, because it carried less than 7 per cent. carbon monoxid. It has a lower candlepower. Coal-gas was made from one relatively small plant in New York. Practically, there was no other water-gas plants outside of New York in this State.

Gas-Leakage.—In New York it amounted to 225,000 cubic feet per mile per annum for six inch mains. This he considered to be very conservative, and could be seen by an examination of the records of which he had a great accumulation, the figures coming principally from the reports of well-managed gas companies. The National Board of Fire-Underwriters presented a large number of figures, in which it was shown that Glasgow had the greatest amount of leakage, 1,643,000 cubic feet per mile per annum. The figures offered showed that large gas leakage was not confined to New York. It was his opinion that the leakage of gas amounted to about 11 per cent. of the output. What becomes of the gas? Any street surface which keeps the water out keeps the gas in. This gas in sewers and excavations may become active and dangerous and cause many explosions. The Park Avenue explosion made him believe that the dynamite explosion was preceded by an explosion of gas which had escaped from the main by leakage. The greater part of the gas by leakage goes into houses by several ways, but primarily from the leakage from the distributing pipes around the fixtures. In small quantities this escapes notice. Recently in Boston in 89 per cent. of all houses inspected there was found from two to ten leaks in the distributing pipes. The result of this leakage was a slow poisoning. The gas may also come from outside the foundation walls, and is more dangerous than leaks elsewhere, because generally unsuspected. Under impervious pavements the gas may be found at great distances from the leaks and in large quantities. This gas about New York was omnipresent and found principally in the cellars, in sewers, in excavations, and even in the soil. A friend of his, while in London, wrote him asking that he inspect the plumbing in his house in Central Park West. He went during the noon hour and, in the cellar, he found the plumber amusing himself by igniting the gas as it escaped through the foundation. This plumber informed him that he could have the same amusement in the cellar of any one of a long row of houses adjoining. In this instance it was found that the street was asphalted close up to the pavement; that the pavement was tight; and that the only outlet for the escaped gas was through the foundation walls of these houses, in the way of least resistance. Gas, too, may get into houses through waste-pipes and house drains.

Effects of Gas-Leakage.—Often this escape of gas was the obscure cause of sickness. Dr. Jackson, in his investigations, found that vertigo and dizziness was caused by a one-tenth of a one per cent. of water-gas, and that, in animals, a little smaller percentage was quite fatal. The habitual exposure to the escaped gas makes good health impossible and sickness inevitable. The risks from gas leakage he classified under three heads: (1) Fire and Explosions; (2) Asphyxia; (3) Blood-poisoning and Anæmia. The occurrence in New York during the past year of a large number of fires and explosions, from a study of all the facts, it was assumed that they were due to leakage from gas mains under impervious pavements. Asphyxia was due to suicidal attempts and "blowing out the gas." In blood poisoning and anæmia gas figures largely, and is assumed to be the root of all the evil produced. Sewer gas consists of atmospheric air carrying simple and compound gases, some existing in the sewer and some coming from without. As a rule, sewer gas was unable to destroy life, because it did not contain or carry disease germs. Of course, sewer-gas may and does carry organisms; but the air outside of sewers contain organisms in greater abundance. Therefore, ordinary sewer gas was better for breathing purposes than that of the street, church, or theatre. Regarding the question of preventing gas leakage it was obviously the first object was to locate it; gas costs less than the measures taken to stop the leakage and, therefore, we can expect no help from the gas companies and no help will ever be gotten from them until the public compels them to seek for and repair the leaks.

Clinical Observations of the Effects of Gas-Leakage.—Dr. SAMUEL LLOYD read this paper. The following cases were reported: Case 1.—A patient, living in a private house, had catarrhal throat trouble; headache, light before the eyes, symptoms of toxic poisoning. Treatment, no effect. Gas poisoning thought of and patient advised to leave the house. Rapid improvement in the general health followed. Case 2.—Patient with temperature ranging from 103° to 105° at night, and 100° to 101° at day. Lungs and heart normal. Bowels regular. No rheumatism or inflammatory conditions present. Liver and spleen somewhat larger than normal. Albumin and occasionally hyaline and granular casts found in urine. A tentative diagnosis of typhoid fever was made. Blood examination showed no Widal reaction, malaria or leucocytosis. A change of air effected a cure in the course of a few days. Case 3.—A sister of Case 2 for two months had a daily rise in temperature. She became anæmic, was constipated, had headaches, general malaise, etc. None of the many drugs taken relieved her. Her organs were all normal, except the spleen, which was one-third larger than normal. Blood examination was negative. A long trip was advised, taken, and a complete cure was effected. The plumber found many breaks in the house and much gas leakage. Case 4.—A girl was told she had miliary tuberculosis. After leaving her place she improved. Case 5.—A girl in the same house as Case 4 gave the same symptoms of anæmia, headache, constipation, coated tongue, pain in the back, etc Leaving the house also effected a cure. Case 6.—The employer of Case 4 and Case 5 presented about the same symptoms, except that the pain in the head was intense and prostration was great. Temperature rose to 104°. With the test of Prof Bayles escaped gas was found in large amounts.

Perez M. Stewart, Superintendent of Buildings, thought it would be a wise plan to equip inspectors with the form of instrument presented by Prof. Bayles. Since January he had done all he could in the various buildings, especially theatres, hotels, etc., in the way of inspections, and he should not be much surprised to learn that the cause of so many fires and explosions was from the acmulation of gas in the cellars and elevator shafts, passing in through the foundation walls; the spark of a match would cause an explosion and quite a panic in a few moments.

Mr. Harry David Gue, the editor of *Insurance Engineering*, and a fire insurance expert, said that there were two hazards to be considered: (1) the property hazard and (2) the hazard to persons. He said that the report of the National Board of Fire Underwriters was the outcome of what could not be kept quiet. This question of gas leakage, so detrimental and dangerous to health, was such a large one to deal with that unless they had co-operation of all, especially of the medical profession, nothing could be done; some concerted action should be taken to attack the danger confronting the public.

Smallpox and Vaccination.—Dr. SAMUEL LLOYD, Chairman of the Committee on Hygiene, made the following report: "The attention of your Committee has been called by the President of the Department of Health of the City of New York to the continued prevalence of smallpox throughout the whole city. It will be seen by a glance at the accompanying table that, contrary to the general idea, that the number of cases is decreasing, the disease is actually on the increase. The census from January 1901, to April, 1902, inclusive, is as follows:

1901	CASES	DEATHS
January	70	10
February	128	32
March	220	37
April	200	40
May	456	66
June	364	71
July	244	80
August	118	35
September	27	10
October	23	11
November	47	7
December	62	11
1902		
January	152	35
February	233	48
March	300	57
April	245	57

It would appear from the records that whereas public vaccinations since January 1, 1902, have proceeded at the rate of 25,000 to 35,000 per week, and have now reached about 550,000 (January 1 to May 17) the public vaccination performed last year was inadequate. Although smallpox last year continued prevalent during the early months of 1901, and reached the maximum for the year 1901 in the week ending May 24, in which week 134 cases were reported; the Health Department last year apparently did not see fit to increase its vaccinations—the weekly total falling off steadily until 8,000 or 9,000 per week was the prevailing figure.

The year's total vaccinations amounted to 383,629, but this year in four and one-half months, nearly 50 per cent. more vaccinations have been performed than in the entire year 1901. The failure to secure adequate vaccination last year, and the fact that smallpox is spread in interior towns through lack of proper vaccination and then transmitted to this city—all these circumstances, together with the bringing of infection by emigrants, tend to a further spread of the disease; and it is a matter for congratulation that the great increase in the number of cases shown last May has not occurred thus far this year. At present the disease persists chiefly among the vagrant class, the members of which are hard to reach, because they leave the lodging-houses and take up their residence each night in a different Raines' Law hotel. The entire vaccinating staff of the Board of Health has several times been called out on emergency duties to cover every lodging house in the city from 4 to 9 A. M., and a large number of vaccinations among lodgers have thus been performed.

It is also reported by your committee that instances of connivance on the part of medical men practising in this city, in hiding cases of smallpox to prevent removal of the patient to the hospitals provided by the Department of Health for the treatment of this disease and the protection of the community, are known. It seems to us, therefore, that this society should take definite action in these premises, and we beg to recommend first, that the attention of the members of the County Medical Society be called to the fact that smallpox is still prevalent in this city and that the number of cases since the 1st of January averages greater than during the corresponding period of last year. Second, that the members of the Society be urged to impress upon all their patients the necessity of vaccination at the present time unless protected by a recent successful vaccination, and that the members of this society co-operate with the Department of Health in every way possible to aid in stamping out the disease. Third, that this Society deprecates any attempt on the part of medical men to hide cases of smallpox, and that they urge at this time, particularly, every member of the profession, to report all cases of contagious diseases to the sanitary authorities at once, in order to make sure of the proper isolation of the patient and his family. Fourth, that the President of the Board of Health be requested to report to this Society any member of the Society who fails to carry out the law in regard to contagion. Fifth, that upon receipt of such a report the case shall be referred to the Committee on Discipline. Sixth, in the opinion of the Committee, it would be wise and would aid materially in the thorough vaccination of all persons not already protected if the Board of Health would serve notice upon the people living in different districts of the city that within a limited time that district will be visited by the vaccinating corps of the Board of Health with the purpose of vaccinating all persons who have not already been vaccinated by their family physician."

Dr. Robert T. Morris asked that some action be taken regarding the escape of fumes of sulphurous acis gas on the Thirty-fourth street electric line of the Metropolitan Traction Company. It was moved and carried that the Committee on Hygiene take action to suppress that nuisance.

Two Unusual Forms of Clonus; Toe Clonus and Lateral Ankle Clonus.—John K. Mitchell reports a case of disseminated sclerosis in which pushing the foot a little to one side instead of upward produced a rapid lateral clonic movement entirely in one plane. Its extreme excursion was not more than three-quarters of an inch, the speed being 6.5 per second. It was difficult to be certain of the special muscles involved. Another point of interest was that any effort to straighten the rigidly half-flexed toes started a toe clonus. It was slow, and was exhausted by eight or ten contractions. If it was excited by carefully pushing up the ungual phalanges with a force too slight to alter the position of the foot, the clonic movement was limited to the toes; if the push were stronger, so that the foot moved on the ankle, ankle clonus appeared. The toe motion was performed by the interossei, the flexor brevis and longus not coming into play.—*Journal of Nervous and Mental Diseases.*

New Instruments.

THE SLOANE MATERNITY MILK SET.

Realizing the fact that a large proportion of the mothers leaving the Sloane Hospital at the end of their puerperium are unable for varied reasons to continue the breast feeding of their babies, and impressed with the difficulty of giving them adequate instruction in the preparation of a proper substitute for breast milk, the writer has adopted the following method, the working of which is shown the mother before she leaves the hospital. The method is based upon three facts:

1. The alkalinity desired in the food is approximately always the same, one ounce of lime water in twenty ounces of food.
2. The sweetness of the diluent desired is usually about the same, one ounce of milk sugar, or one-half ounce of granulated (cane) sugar, in twenty ounces of food.
3. Ten ounces of milk taken from the top of a quart bottle of milk, bottled the night before, or which has stood for six hours on the ice, contains when mixed, approximately, 10 per cent. of fat, *i. e.*, = 10 per cent. milk, containing Fat 10.; Sugar 4.50; Proteid 3.50. Furthermore sixteen ounces of milk taken from the top of the bottle under similar conditions contains, when mixed, approximately 7 per cent. of fat, *i. e.*, = 7 per cent. milk, containing Fat 7.; Sugar 4.50; Proteid 3.50.

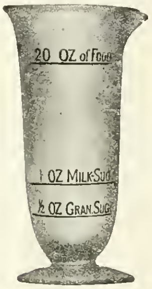

Fig. 1.

Fig. 2.

According to Holt.

	FAT	SUGAR	PROTEID
1 oz. of 10 per cent. milk diluted to 20 oz. with a diluent containing 1 oz. milk sugar gives.....	.50	5.20	.17
2 oz. of 10 per cent. milk diluted to 20 oz. with a diluent containing 1 oz. milk sugar gives.....	1.	5.40	.33
3 oz. of 10 per cent. milk diluted to 20 oz. with a diluent containing 1 oz. milk sugar gives.....	1.50	5.60	.50
4 oz. of 10 per cent. milk diluted to 20 oz. with a diluent containing 1 oz. milk sugar gives.....	2.00	5.85	.66
5 oz. of 10 per cent. milk diluted to 20 oz. with a diluent containing 1 oz. milk sugar gives.....	2.50	6.05	.83
6 oz. of 10 per cent. milk diluted to 20 oz. with a diluent containing 1 oz. milk sugar gives.....	3.	6.25	1.
7 oz. of 10 per cent. milk diluted to 20 oz. with a diluent containing 1 oz. milk sugar gives.....	3.50	6.50	1.20
10 oz. of 7 per cent. milk diluted to 20 oz. with a diluent containing 1 oz. milk sugar gives.....	3.50	7.10	1.75

With a graduate holding twenty ounces of food and marked for one oz. of milk sugar (or where expense is an important item, one-half oz. of granulated sugar) and a Chapin dipper (modified in shape by Dr. Addison W. Baird) for removing the top milk from the bottle, one can gradually increase the strength of food as needed for the growing baby.

The method is so simple that it is easily understood by almost any mother and the small cost of the apparatus places it within the reach of all. It is manufactured by James T. Dougherty of this city.

The following directions accompany the apparatus:

The set consists of a measuring glass holding twenty ounces (see Fig. I), and a metal dipper (called the Chapin dipper) holding one fluid ounce (see Fig. II).

Directions for use.—Get a quart bottle of good milk and let it stand on ice or in a cool place for half an hour so that the cream will show at the top of the bottle. From the upper part of the bottle are obtained two kinds of top milk:

Top milk No. I, obtained by taking ten dipperfuls from the top of the bottle, the first dipper being filled with a spoon to prevent spilling, the remaining nine dipperfuls being taken by dipping carefully from the bottle. These ten dipperfuls are to be mixed in a clean pitcher, and from the milk thus mixed the baby's food may be prepared until it is from four to six months old.

Top milk No. II, obtained by taking sixteen dipperfuls from the top of the bottle, the first dipper being filled as before with a spoon, the remaining fifteen dipperfuls being taken by dipping carefully from the bottle.

These sixteen dipperfuls are to be mixed in a clean pitcher, and from the milk thus mixed the baby's food may be prepared from the age of about four months until it is a year old.

In using this milk set, whatever strength of food is desired, the sugar and the lime water are always the same: one ounce of milk sugar (or one-half ounce of granulated sugar) and one ounce (one dipperful) of lime water. The quantity of food made by filling the glass once is always the same—twenty ounces. The strength of the food varies with the number of dipperfuls of top milk used.

Preparation of the food.—First. Into the measuring glass pour milk sugar up to the line marked one ounce milk sugar, or granulated sugar up to the line marked one-half ounce granulated sugar.

Second. Add one dipperful of lime water and mix by shaking the glass.

Third. Add the required number of dipperfuls of top milk according to the age of the baby as explained below.

Fourth. Fill the measuring glass up to the line marked twenty ounces of food, with water, either plain or barley water, or oatmeal water.

During the first month it is usually better to use plain water, after that barley water, or if the baby is very constipated, oatmeal water.

Strength of food for different months.—First day—Give no milk; put in milk sugar to mark, then fill with boiled water. Second day—Add one dipperful of top milk No. I. Third day—Add two dipperfuls of top milk No. I.—Fourth day—Add three dipperfuls of top milk No. I. Fifth to tenth day—Add four dipperfuls of top milk No. I. Tenth to thirtieth day—Add five dipperfuls of top milk No. I. One month to two months—Add six dipperfuls of top milk No. I. Two months to four months—Add seven dipperfuls of top milk No. I. Four months to nine months—Add ten dipperfuls of top milk No. II.

When the baby needs more than twenty ounces in the twenty-four hours, fill the measuring glass twice instead of once, before putting the food into the baby's bottle.

After nine months the food is prepared by shaking the quart bottle of milk when first obtained and using the plain mixed milk.

After preparing the food put it (especially in hot weather) on the stove and heat it till it simmers. It is then ready to be placed in the baby's bottles which have been thoroughly washed in hot soapsuds and rinsed.

The above directions are given for an average healthy baby. A frail baby, or one whose weight is below the average, will need to have the strength of food increased more slowly. A very strong healthy baby may have the strength of the food increased more rapidly. If the stronger food does not seem to agree with the baby, decrease the number of dipperfuls of milk used.

By increasing or decreasing the number of dipperfuls of milk, the food can usually be adjusted to the child's digestion.

Amount of food at each feeding for different ages.—First week, ½ to 1½ ounces. Second and third weeks, 1½ to 3 ounces. Fourth and fifth weeks, 2½ to 3½ ounces. Sixth to ninth week, 3 to 4½ ounces. Third to fifth month, 4 to 5½ ounces. Fifth to ninth month, 5½ to 7 ounces. Ninth to twelfth month, 7 to 9 ounces.

Medical Items.

Case of Impacted Urethral Calculus in a Boy of Four Years.—The patient of J. S. Triplett suffered much pain in the hypogastric region, and was unable to pass his urine. Catheterization with a soft instrument was unsuccessfully tried. Finally, examination with a metallic instrument enabled a diagnosis to be made, under anæsthesia, of impacted calculus. During the examination, considerable urine was voided. Next day a median lithotomy was done, and a stone was found imbedded in the bulbous portion of the urethra. It weighed, in the dried state, seven and a half grains, and was one and one-eighth inches in greatest circumference. Recovery was somewhat tedious, but finally resulted.—*St. Louis Medical Review.*

Civilization and Birth Rate.—M. Neymarck has lately examined various economic, financial and social causes that influence the birth rate. Some of his results are summarized in what follows: He believes, in the first place, that the birth rate will always diminish with the increase of "civilization," with "progress," in a country. In Germany the birth rate was 42 per 1,000 in 1875; in 1895 it was 36. In England the rate diminished from 36 to 29 in the same period. In France it fell from 26 to 25.2. The rate of diminution is, therefore, least in France. Some of the economical causes influencing the birth rate are:

First—The increased cost of living, or, more accurately, the increased scale of comfort. As a matter of fact, it is not certain that the cost of life has increased, but our requirements have become greater.

Second—The desire to insure increased comfort for one's self and one's family. "The father of a family limits his offspring in proportion to his egoism."

Third—The desire to establish one's children well in life is proved by curious statistics. In France there were 281,353 heritages in the direct line to divide 3,469 millions of francs; of these 170,819 heritages, amounting to 2,131 millions, were allotted to one or two children; 75,961, amounting to 926 millions, were divided between three or four children, and 34,573, amounting to 412 millions, were divided between five or more children.

Fourth—The reduction of the rate of interest runs parallel to the decrease in birth rate. In France the birth rate was, in 1872, 27.8 per 1,000; in 1880, 25.6; in 1890, 22.9; in 1900, 22.4. The 3 per cents. produced, in 1871, about 5½ per cent. on the investment; in 1880, about 3½ per cent.; in 1890, about 3¼ per cent.; in 1900, less than 3 per cent.

Fifth—The increase of taxes and the indirect effect of the obligations of military service must also be considered.

Sixth—The entrance of women into competition with men as wage-earners. In France there are now 3,353,831 women who are thinking less of maternity, as they are more or less interested in their professions or trades. There are 3,861,599 single women, 1,808,838 families without children, 3,000,000 divorced or widowed persons without children—nearly 6,000,000 persons in all these categories.—*New York Sun.*

Expectation of Life.—From the experience of life insurance companies, and from census returns, tables of the average expectation of life can be constructed. A sample of such a table is given below. Column I is the age; Column II is the expectation of after life from the experience of England and Wales in 1838-54; Column III is the expectation from the experience of Massachusetts in 1893-97. · The statistics apply to males:

I. *Age.*	II. *England.* 1838-54.	III. *Mass.* 1893-7.
0 years.	39.91 years.	44.09 years.
10 years.	47.05 years.	49.33 years.
20 years.	39.48 years.	41.20 years.
30 years.	32.76 years.	34.28 years.
40 years.	26.06 years.	27.41 years.
50 years.	19.54 years.	20.53 years.
60 years.	13.53 years.	14.38 years.
70 years.	8.45 years.	9.34 years.

Corresponding tables for the two epochs in other countries agree substantially with the foregoing. The expectation of life under modern conditions has increased. A male exposed through life to the conditions of mortality obtaining in Massachusetts in 1893-97 would, on the average, live 4.08 years longer than he would have lived had he been subjected to the rates prevalent in England and Wales in 1838-54. The increased expectation of life is greatest in the earlier years, as the table shows. It does not prove that our stock is more vigorous, but it points to the undoubted fact that our weaklings are better cared for by improved sanitation. A decrease in the birth rate tends to make the expectation larger, for it is among infants that the greatest mortality obtains. Consumption is the dreaded disease that carries off great numbers of all ages. Modern medicine is on the way to conquer that plague, and within a comparatively short period we may look for great increases in the tables of expectation.—*New York Sun.*

New Building for Scientific Purposes at Yale University.—The amount of the gift by a donor, not named, for a new scientific building for the Sheffield Scientific School is about $75,000. The new building, with three floors and a basement given up respectively to mineralogy, geology, physical geography, and mining, will have 95 feet front and 65 feet depth, and will be placed next to the old Sheffield residence on the campus of the school. This leaves vacant a large plot at the corner of Grove street and Hillhouse avenue, where a greater building can be placed. The plan, in a general way, outlines the future physical development of the school, in the form either of a quadrangle or arcade of about 400 x 600 feet, the purchase of but one building being now required for the complete ownership of the whole area. In future years, probably, the old Sheffield residence, now used as a biological laboratory, and the original school building, earlier used as a medical school, will come down to make way for modern structures.

The Muscular Factors Concerned in Ankle Clonus.—S. Weir Mitchell recently observed in a case of trauma of the spinal cord that the very remarkable ankle clonus present was the work of the soleus muscle alone, the gastrocnemius being entirely passive. Further observation of other cases showed that the first one was not exceptional, as in all of them the soleus alone was active in clonus of the ankle. The explanation of the lack of response on the part of the gastrocnemius appears to consist in the fact that, in spite of their common insertion, the soleus and the gastrocnemius have distinct purposes, as stated in Duchenne's "Electro-Physiologie": "When the leg is flexed on the thigh, the gastrocnemius is so relaxed by reason of its upper hold on the femur as to lose almost all power to extend the foot. The soleus, then, because of its attachment to the tibia, is still left competent to extend the foot." Another and singular fact which is possibly involved in the absence of clonic response by the gastrocnemius is that there is normally a difference in irritability between different muscles. Hence, one additional reason why the gastrocnemius cannot be made to respond in any position may be that it is simply less excitable than the soleus.—*Journal of Nervous and Mental Diseases.*

Cook's Method of Uric-Acid Estimation.—To 10 c.c. of urine add 0.5 to 1.0 gms. of sodium carbonate and ammonium hydrate 1-2 c.c. Centrifuge and pour clear urine into tube. Add and mix ammonium hydrate 2 c.c., sol. ag. NO_3, 5 per cent., 2 c.c. Centrifuge. Again add ammonium, and the solution is centrifuged till the minimæ reading is obtained. One c.c. of ppt. represents 0.001176 gm. of uric acid in 10 c.c. urine, and the percentage is obtained by multiplying the total amount by 10.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended June 28, 1902:

NOTES ON A FEW CASES OF HODGKIN'S DISEASE AND LYMPHATIC LEUKÆMIA.*

BY MAX EINHORN, M.D.,
NEW YORK.
PROFESSOR OF MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

ALTHOUGH neither Hodgkin's disease nor lymphatic leukæmia is so very rare, yet I would like to communicate here a few cases of both conditions that have come under my personal observation, and, in connection with them, to add a few remarks.

To Hodgkin[1] belongs the credit of having first called attention to cases characterized by a general swelling of the glands, accompanied by an enlargement of the spleen and frequently also of the liver, and which always ended fatally.

In his well-known work Hodgkin says, "All these cases agree in the remarkable enlargement of the absorbent glands accompanying the larger arteries, viz., the glandulæ concatenatæ in the neck, the axillary and inguinal glands, and those accompanying the aorta in the thorax and abdomen." This glandular swelling, according to Hodgkin, is a primary affection for the following reasons: "Notwithstanding the different characters which this enlargement may present, it appears in nearly all cases to consist of a pretty uniform texture throughout, and this seems rather to be the consequence of a general increase of every part of the gland than of a new structure developed within it, and pushing the original structure aside, as when ordinary tuberculous matter is deposited in these bodies." In all his cases Hodgkin found the spleen also diseased.

After Virchow[2] had published his classic work on leukæmia, it became desirable to examine the condition of the blood in cases similar to those described by Hodgkin. Bonfils[3] was the first to do this, and showed that the blood was normal in these patients.

Later Wilks[4] described cases analogous to the above which occurred in his own practice, designating them as "Hodgkin's disease."

Regarding the pathology of these cases, Wilks expresses himself as follows: "The generally accepted doctrine has been that an affection like the present must be constitutional; but modern research would quite approve of the theory which should make it commence in one part of the lymphatic system, and from this, as a source of contamination, be propagated through the body." Wilks closes his work with the following words: "It will be seen, that of the fifteen cases here given, how remarkably alike were the features in all; consisting of an enlargement of the lymphatic glands, with a peculiar deposit in the organs, and more especially the spleen. Amongst these cases were two in which there was no affection of the spleen, one in which the organ was hypertrophied, and one in which it was lardaceous. In the remaining thirteen cases the disease was of a remarkably uniform character, and quite deserving of a special name; all the cases which I have described having come under my own eye, and resembling in all particulars the first four, which Dr. Hodgkin so many years ago brought under the notice of the profession."

Cohnheim[5] in describing a case of Hodgkin's disease, was the first to use the expression, "pseudoleukæmia," to signify at once its resemblance to, and its distinction from, true leukæmia. He relates the case of a man forty-two years of age, suffering from enlargement of the spleen and glands, with quite a normal condition of the blood. Two years previously he had suffered from intermittent fever, and later complained of pain in the left side. Death occurred from exhaustion preceded by ascites, etc. Cohnheim recognizes the difficulty of differentiating between leukæmia and pseudoleukæmia when he says: "Should we assume that the short duration of the disease, hardly three months, has not allowed typical leukæmic blood changes to develop, and thus has obscured the whole case?"

Wunderlich[6] reports three cases of pseudoleukæmia, and gives an excellent description of the disease: "There is a peculiar form of disease," he remarks, "characterized mainly by tumefactions of the external and internal lymph glands, which gradually increase and partially assume colossal proportions. Besides, we usually find early in the disease peculiar firm deposits in various internal organs, most frequently the spleen, next the liver, more rarely the kidneys, the glands of the stomach, the intestinal follicles, the lungs, the pharynx, etc. The disease develops, as far as our present observations go, without any known cause, is accompanied by a high degree of anæmia, without any increase in the number of leucocytes, by moderate ascites, general exhaustion, and sometimes by the development of diphtheritic processes. If far advanced, death is probably inevitable, and usually occurs sooner than with true leukæmia. At an early stage the disease may be amenable to suitable treatment."

If the enlargement of the spleen is more prominent than that of the glands we call the disease anæmia splenica, according to Strümpel[7]. Cases of primary splenomegaly, first described by Gaucher[8] and more recently by Bovaird,[9] and Brill,[10] probably also belong here.

Banti's disease[11] (characterized first by splenic tumor, later by enlargement of the liver and ascites) is probably also only a variety of Hodgkin's disease.

It would be beyond the purpose of this short paper to review the whole literature of these conditions. I will, however, refer to some of the more recent investigations regarding pseudoleukæmia.

Cases of Hodgkin's disease or pseudoleukæmia resemble lymphatic leukæmia to such a degree that some authors consider them identical.

A transition from pseudoleukæmia into true leukæmia was first observed by Fleischer and Penzoldt,[12] and later by Mosler.[13]

---

*Read before the German Medical Society of New York.

Westphal[14] expresses himself on this point as follows: "We are therefore able to record one case of transition from pseudoleukæmia to true leukæmia, and one case of transition from beginning leukæmia to pseudoleukæmia, and to note resemblances only to the symptom complex of essential pernicious anæmia. These circumstances seem to be of interest with reference to the transitional forms described in literature. According to our experience they are quite rare and are unable to throw any light upon the obscure point in the pathology of pseudoleukæmia, the disproportion in the condition of the blood and the blood-producing organs." As a result of his work, Westphal reaches the following conclusions:

1. Pseudoleukæmia is most probably an infectious disease.

2. A direct connection with tuberculosis is improbable; thorough bacteriological investigations and inoculation experiments would have to decide this question.

3. In a number of cases certain local affections, especially of the mouth and its surroundings, seem to be starting points of the pseudoleukæmic process.

4. Cases encroaching upon the realm of leukæmia and pernicious anæmia occur, but are rare according to our experience.

Martin and Mathewson[15] pointed out the difficulty of drawing sharp distinctions between lymphatic leukæmia and Hodgkin's disease. They say: "It by no means infrequently happens that in cases of multiple lymphomata the number of white cells borders so closely upon the ratio found in leukæmia that we are in doubt as to the presence of a true leukæmia or of an ordinary leucocytosis. Of all forms of leukæmia, that which is most akin to Hodgkin's disease is, of course, the lymphatic form." Then follows the description of a case in which the proportion between the white and the red blood-corpuscles varied between 1 to 75 and 1 to 120. These authors also mention a case of general lymphomatosis, in which at one time a leukæmia was temporarily present: "The blood examination on his admission revealed 3,166,000 red cells, 8,000 white, and 42 per cent. of hæmoglobin. For the first two weeks of his sojourn in the hospital the patient improved, the leucocytes were not markedly increased at any time, nor were there any other notable changes. Suddenly, however, on the fifteenth day after entry, there was a marked change, with increased fever, recurrent hemorrhages from the nose, and the blood examination within two days showed over 60,000 white cells to the c.mm. This leucocytosis persisted for a week, the patient's condition otherwise getting progressively and rapidly worse. Life was prolonged for about one week more, and during that period the leucocytes again diminished in number, returning in about two days to normal, and on the day previous to death an estimate showed nearly 14,000 to the c.mm.

"In the illness then, which lasted, in all, about six weeks, there was a period where undoubtedly all the typical signs of acute leukæmia were present, while on other occasions the examination revealed the usual classical symptoms of acute Hodgkin's disease."

According to Pinkus[16] the relative proportion of lymphocytes to the other white blood cells must be increased in true pseudoleukæmia. This brings lymphatic leukæmia and Hodgkin's disease into still closer relations. For, according to Pinkus, lymphatic leukæmia represents a disease whose principal symptom consists in the blood change, characterized by an increase of lymphocytes and in the tumor-like enlargement of lymphatic organs. Regarding the increase of lymphocytes in the blood, it is less the absolute number of these cells than the relative increase with regard to the other forms of leucocytes that is of importance. The decisive point is always, as Ehrlich[17] has taught us, the qualitative change from normal, aside from the increase of leucocytes, the specific pathognomonic variety of leucocytosis. Generally speaking, the boundary line, according to Pinkus, lies somewhere between the proportions of W:R=1:100 and 1:200. Cases presenting smaller quotients would have to be counted as pseudoleukæmia, whereas larger ones would have to be considered as true leukæmia.

Pinkus divides cases of pseudoleukæmia into three forms:

1. True pseudoleukæmia. In this class we find the cases with generalized lymphomatosis and relative lymphocytosis, which have to be considered in one group with true lymphatic leukæmia.

2. Lymphosarcomatosis, generalized lymphomatosis without blood changes or even with decrease in the percentage of lymphocytes, and with the characteristics of malignant tumors.

3. Other not purely lymphatic affections of the lymphatic apparatus, tuberculosis, malignant tumors.

Becker[18] is of the opinion that the same pathological process is the cause of pseudoleukæmia and of lymphatic leukæmia, and that the presence of a larger or smaller number of lymphocytes in the blood is a secondary matter, the reason for which cannot at present be satisfactorily explained. If this is the case, we must discard the expression pseudoleukæmia and adopt for the designation of the anatomical process some such name as lymphomatosis diffusa, which may again be subdivided into aleukæmica and leukæmica, acute and chronic, perhaps also lienalis, adenoidea, and myeloidea.

According to Cabot[19] the pathology of leukæmia and Hodgkin's disease is identical but for the blood count. In Hodgkin's disease the blood is normal, or shows, at most, a moderate anæmia or leucocytosis (adult cells alone increased), and the diagnosis is easily made.

Bramwell[20] discusses this question as follows: "The exact relationship of the lymphatic form of leucocythæmia to Hodgkin's disease has not yet been satisfactorily determined. To the naked eye the glandular lesions in the lymphatic form of leucocythæmia and in Hodgkin's disease are very similar, and some observers state that they are identical in character; but, so far as my observation enables me to judge, the enormous glandular enlargements which are met with in some cases of Hodgkin's disease are never developed in cases of lymphatic leucocythæmia."

Sternberg[21] has pointed out the difficulty of strictly differentiating pseudoleukæmia from tuberculosis of the lymphatic apparatus.

Bramwell also expresses himself in a similar manner by saying: "I have seen several cases of this kind and have been so impressed with the difficulty that there is in some cases, more especially in children and in young subjects, of differentiating during life the glandular enlargements due to Hodgkin's disease from those due to tubercle, that I now have great hesitation in committing myself to a definite diagnosis of Hodgkin's disease and in excluding tubercle, unless the spleen is distinctly enlarged or unless there is evidence of the presence of lymphoid deposits in the other organs and tissues."

Regarding the differential diagnosis, Osler[22] says: "A single bunch in the neck, particularly if submaxillary, persisting for over a year or eighteen months without involvement, however slight, of the glands on the same or the opposite side, or in the axilla, is almost certainly non-malignant lymphoma."

Fischer[23] describes Hodgkin's disease under the name of "malignant lymphoma," which was first introduced by Billroth. Fischer advocates the use of this term as the clinical character of the disease is best designated by it, and nothing is implied regarding the kind of tumors, the etiology of which, as well as of their mestastases, is not yet sufficiently clear.

Fischer examined the blood and freshly excised glands from twelve patients. In all cases the blood was free from microorganisms, the culture media remaining sterile; microscopical as well as bacteriological examination of the lymph glands also gave negative results; animals in which Fischer implanted small pieces of glands, still warm, remained healthy. He thinks that tuberculosis of the lymph glands in cases of malignant lymphoma is to be looked upon as a secondary infection. The organism, that has already been weakened by the development of the malignant lymphoma, is unable to resist the invasion and harmful results of the tubercle bacillus.

As will be seen from the literature referred to, the etiology of the disease is just as obscure now as it was at the time when Hodgkin published his first observations. We, furthermore, have to deal with various differences of opinion regarding the relation of pseudoleukæmia to lymphatic leukæmia. Some of my cases of Hodgkin's disease have been observed for years; accurate blood examinations have also been made. It will, therefore, be of interest, after sketching them shortly to compare them with two cases of lymphatic leukæmia which I treated at about the same time. I will now present the histories of the cases:

CASES OF HODGKIN'S DISEASE.

CASE I.—May, 1895. Simon U., forty-eight years old, has complained for a year of great weakness, at times dizziness and slight dyspeptic symptoms, such as belching, feeling of fulness and constipation.

Status præsens: Patient is of small stature and slim appearance; face somewhat pale; color of lips pale red. The cervical glands are slightly swollen, of the size of a hazelnut. The same applies to the inguinal glands, whereas, in the axillæ no tumefaction can be felt.

Thoracic organs are normal. The palpation of the abdomen shows that the stomach lies somewhat to the right, its lower boundary reaching to one finger's width below the navel. Extending from the left hypochondrium nearly throughout the whole left half of the abdominal cavity, a tumor can be made out, having an elongated oval shape and merging directly into the area of splenic dulness. The surface of this immensely enlarged spleen feels quite smooth, but harder than normally. The liver reaches in the right mammillary line two fingers' width below the margin of the ribs.

A blood examination shows nothing pointing to leukæmia. The urine is free from albumin and sugar. Knee reflexes are present; temperature and pulse show nothing abnormal.

The patient was treated alternately with methylene blue and with arsenic and iron, without any appreciable change in his condition. This state lasted about two years, when the patient suddenly took ill with symptoms of peritonitis (perforation?) and died four days later.

The abdominal organs shortly before death showed no change from the condition mentioned above, with the exception of the presence of a small degree of ascites.

CASE II.—May 17, 1901. Ignatz F., forty-five years old, merchant, was always well up to three and a half years ago. He has never had syphilis, but was always a heavy smoker, and a moderate drinker. Three and one-quarter years ago he began to complain of stomach pains, irregular bowels and poor appetite. In spite of repeated washing of the stomach, his condition did not improve. Three years ago he came to me complaining principally of a dry cough and digestive disturbances. I was then able to make out a somewhat enlarged liver and a slight swelling of the spleen. I had the opportunity of seeing the patient about twice weekly for some time. The spleen grew visibly; while at first hardly palpable, it increased with such rapidity that in five or six weeks it filled the larger part of the left half of the abdominal cavity. Two and a half years ago he had fever with much cough and dyspnœa. At the same time large furuncles began to appear in various places of his body. A year ago he had another similar attack, lasting nearly a week. One-half year ago, suddenly, while eating supper, he experienced a severe pain in the stomach, vomited and felt very badly. Twelve days later a similar attack developed in the afternoon, but of greater intensity. He was bathed in a cold perspiration, felt cold and thought that he was going to die. A little later, however, he felt better again. Since then he has been free from these attacks up to two weeks ago when he had another. Since his first attack he complains of dizziness, frequently of an annoying cough and sometimes of pains in the legs.

Status præsens: the patient looks well nourished and shows a good healthy color in his cheeks. Color of lips a trifle less red than normal. Tongue only slightly coated. On inspection the submaxillary region reveals a slight protrusion below the inferior maxilla. This, on palpation, is found to be caused by a swelling of the glands. The cervical glands are enlarged, but especially the inguinal glands, which are visible to the eye as prominent masses.

The thoracic organs are found to be normal on physical examination. The area of heart dulness is not enlarged and the heart sounds are clear.

Palpation of the abdomen does not reveal tender spots anywhere. The stomach extends in the linea alba down to the navel, as shown by the splashing sound produced over this region. The organ has been crowded away from its place in the left hypochondrium by the spleen. The latter can be plainly felt in the left half of the abdomen as a somewhat hard elongated tumor with a grooved surface. Its boundaries, as determined above by percussion, below by palpation, are as follows: In the left axillary line splenic dulness begins above the seventh rib and can be followed downward up to a hand's width below the navel. In the whole region, *i. e.* from the left costal margin downward, the spleen may be plainly palpated up to the point indicated. The width of the spleen from below the ribs up to the umbilical line is about 14 to 15 cm., from the umbilicus downward it gradually becomes less and is only 10 cm. at its lower extremity. Its length measured in the mammillary line is 33 cm. The liver is also enlarged and may be traced down to two fingers' breadth below the right costal margin. (Figure 1.) On standing, the abdomen protrudes somewhat in its lower portions; fluid, however, cannot be demonstrated by percussion.

The urine is normal. The principal complaints of the patient at present refer to the intense pains in all bones (legs, arms, back, sacrum, head), especially in the morning on awakening, less during the day on slight exertion. The appetite is not especially good, bowels not very regular. Knee reflexes are present.

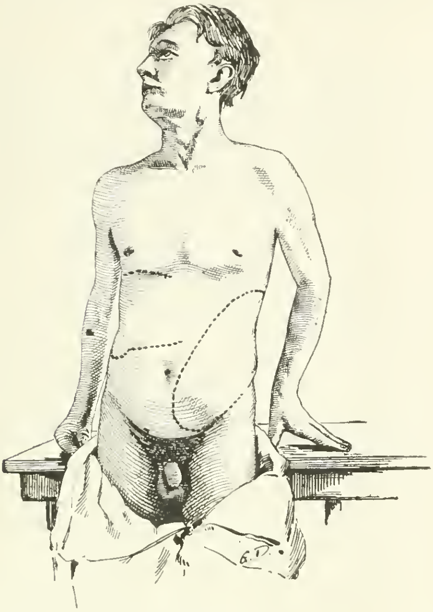

FIGURE 1.—IGNATZ F.
(Photograph, face changed.)

November 21, 1900.—Blood examination shows a diminution of hæmoglobin. Red blood-corpuscles somewhat pale, leucocytes not increased; one normoblast, a few polychromatophile red blood cells.

November 20, 1901.—The patient complains a great deal of a dry cough, headache and pain in the bones on awakening. Appetite is not bad, bowels constipated.

Status præsens: spleen extends down to within three fingers' width of the os pubis, filling the left half of the abdominal cavity to within two fingers' breadth of the linea alba. In the thorax splenic dulness begins at the seventh rib. The surface of the spleen feels somewhat hard and uneven. In some places slight protuberances can be felt. The liver reaches about two fingers' width below the right costal margin. The inguinal and cervical glands have not changed much since their condition was observed the last time. Knee reflexes are present. All the bones are sensitive to pressure. Pulse, 80; temperature, 98°F. (Patient says he had fever last night).

Blood examination: Hæmoglobin, 72 per cent.; red blood cells, 4,110,000; white blood cells, 6,300

A differential count of the leucocytes gives the following result:

Polymorphonuclear	37	per cent.
Small lymphocytes	37	"
Large lymphocytes	20	"
Mononuclears	2	"
Eosinophiles	2	"
Myelocytes	2	"

November 10, 1901.—The submaxillary glands are a trifle larger and several of the cervical glands' especially on the left side, stand out more prominently. The axillary glands, also seem to be somewhat larger, otherwise there is no material change in the condition of the patient. He now principally complains of pain in the limbs, dry cough and rapid fatigue either at his occupation or when walking. He can walk only four to five blocks. He complains of a feeling of heat in the head. Pulse, 84, regular, somewhat small; temperature, 97.2° (mouth). Urine negative, specific gravity 1011. Stomach contents (one and one-half hours after test breakfast) show only a trace of HCl (Toepfer) after diluting it twice.

CASE III.—July 9, 1901. Morris F., thirty-two years old, merchant, had malaria about eleven years ago while in the South; three years later he had another attack. Six to seven years ago he began to suffer from constipation. His appetite remained good. Gradually the constipation grew worse; he began to complain of headache, suffered from sleeplessness caused by shortness of breath and palpitation of the heart. In the last six weeks he has lost eight pounds. If he eats much he has a bloated feeling and must put his finger in his throat in order to relieve himself by vomiting.

Status præsens: between the ensiform process and the navel a protuberance is visible, beginning about one inch below the ensiform process and terminating about two to three fingers' width above the navel. Palpation shows that the mass is continuous with the liver. The dulness of this organ begins in the right thoracic cavity at the upper border of the eighth rib. The liver extends toward the left nearly to the mammillary line. The spleen can be felt plainly as an elongated flat mass in the mammillary line and somewhat to the left of it, extending to four fingers' width beyond the free costal margin (Figure 2.) In the axillary line the

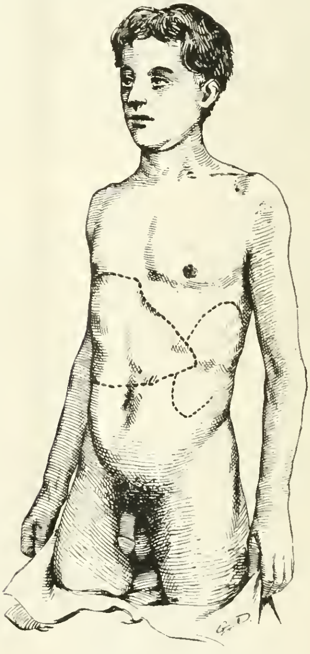

FIGURE 2.—MORRIS F.
(Photograph, face changed.)

splenic dulness can be demonstrated by percussion from the eighth rib downward. In the right inguinal region there is a tumefaction caused by enlargement of the glands. The cervical glands are also considerably swollen. Urine is negative.

Blood examination: Hæmoglobin, 83 per cent.; red blood cells. 5,045,000; white blood cells, 6,600.

Polymorphonuclear	69	per cent.
Small lymphocytes	19	"
Large lymphocytes	7	"
Mononuclear	1	"
Eosinophiles	4	"

Examination of the stomach contents, one hour after test breakfast showed presence of HCl., and total acidity=40.

December 12, 1901.—Spleen 25 cm. long, 13 cm. broad. Submaxillary, cervical and inguinal glands swollen. He has never had a chancre.

Examination one hour after test breakfast shows: HCl=O, reaction hardly acid. Particles of roll coarse, no fluid.

CASE IV.—November 3, 1901. Meyer N., fifty-two years old, merchant, has always been well until eleven weeks ago, when he noticed that the glands in his right inguinal region were swollen. He had severe diarrhœa at the same time, lasting several weeks and complained of tension in the abdomen. He was feeling very weak, and complained of vertigo. A tendency to diarrhœa remained. He has not lost in weight. He sleeps well, but his appetite is not especially good. He complains of some cough. Lately his wife found that his face was somewhat swollen in the morning.

Status præsens: submaxillary glands on both sides swollen, also cervical and supraclavicular glands. On the right as well as on the left side of the neck a gland of about the size of a hazelnut can be felt. The axillary glands are much swollen, about the size of a goose's egg. The inguinal glands on both sides are also enlarged, each bunch being somewhat larger than a hen's egg. Area of cardiac dulness is not enlarged. The patient had a severe cough several weeks ago, which has disappeared, and his thoracic organs are normal. Color of lips and cheeks is pale. The spleen is much enlarged; it can be palpated two fingers' width below the left margin of the ribs, and feels a little harder than normal, without, however, showing any nodosities. Splenic dulness above commences somewhat higher than normally. The liver in the right mammillary line extends three to four fingers' width below the costal margin, and feels harder than normal, without any nodules. Hepatic dulness begins in the thorax at the sixth rib. In the abdomen above the left inguinal region there is a bunch of glands larger than a hen's egg; on the right side only small glands of the size of a hazelnut can be felt. Knee reflexes normal, tongue slightly coated; urine negative, specific gravity, 1,009.

Blood examination: September 30, 1901, Hæmoglobin. 76 per cent., red blood cells, 4,750,000; white blood cells, 7,300.

	IX. 30 = 01.		XI. 3 = 01.	
Polymorphonuclear	46	per cent.	58.6	per cent.
Small lymphocytes	22	"	18.4	"
Large lymphocytes	8	"	5	"
Mononuclear	8	"	5	"
Eosinophiles	10	"	12.4	"
Mastcellen	6	"	6	"

Examination of the stomach after breakfast shows the presence of free HCl.

Although I have observed four other cases of probable Hodgkin's disease, I will not enter into details, but will only say that in two the spleen, liver and glands were swollen, without, however, attaining any specially large size; that in the other two there were lymphomata (in one patient only on the right side of the neck; in another in the axillæ and elbows) without splenic or hepatic enlargement. In this paper it has been my object to discuss more particularly those cases of Hodgkin's disease characterized by splenic and hepatic enlargement, and which particularly resemble leukæmia.

CASES OF LYMPHATIC LEUKÆMIA.

CASE I.*—November 20, 1899. Jennie B., nine years old, was born at eight months. The patient was always quite healthy up to several months ago when she became weak. She has lately been suffering from diarrhœa, for which she was brought to me.

Status præsens: Patient does not look particularly pale. Thoracic organs intact. Inspection shows a considerable enlargement of the abdomen, and palpation reveals the presence of a rather large splenic tumor, filling the upper part of the left half of the abdominal cavity. It is of rather firm consistency. The liver is enlarged and extends nearly two fingers' width below the margin of the ribs in the right mammillary line. The cervical and inguinal glands are swollen. The blood, taken from the finger, looks pale. Microscopically, it shows the features of lymphatic leukæmia. The estimation of the number of red and white blood cells was made from the stained specimen after a method soon to be published by Dr. Laporte and myself, and gave the following results: red blood cells, 3,360,000; white blood cells, 389,000. The relation of the white to the red is about as 1 : 8. A differential count of the white cells shows:

Polymorphonuclear	1	per cent.
Small lymphocytes	48.7	"
Large lymphocytes	49	"
Mononuclear	1.3	"

CASE II.—October 23, 1901. Mrs. Paula K., fifty-two years old, has complained for the last four months of a great deal of pain in the stomach and of diarrhœa. The patient has lost in weight and feels quite weak. Cough has been present for three months; it is dry and not accompanied by expectoration. She sleeps well. Patient now chiefly complains of pains in the abdomen and weakness.

Status præsens: Patient looks pale. The lips are of a light red color. On both sides of the throat, directly under the jaw, small protuberances of about the size of a pigeon's egg are visible. The supraclavicular region shows on the left side several glandular swellings. In the axilla on both sides there are also tumors, but of larger dimensions (size of hen's egg). In the inguinal region on both sides several round bunches of glands are visible. On palpation the spleen is found to be much enlarged. It begins in the thorax on the left side in its normal place, as can be demonstrated by percussion; it extends downward to about three fingers' width below the navel, filling the left part of the abdominal cavity to within three fingers' breadth of the linea alba (Fig. 3). On palpation the spleen feels rather hard, giving the impression of an uneven surface without any distinct nodules. The stomach extends down to the navel, as can be demonstrated by the splashing sound. The liver is enlarged and reaches, in the right mammillary line, three fingers' width below the costal margin. Knee reflexes are present.

Thoracic examination: slight dulness on the left side, no râles; somewhat diminished breathing;

---

*This case was presented by me at a meeting of the German Medical Society of New York, December 4, 1899.

heart sounds normal. Pulse, 80; temperature, 98.5°F.

Blood examination: hæmoglobin, 68 per cent.; red blood cells, 4,850,000; white blood cells, 152,000.

Polymorphonuclear	5.6	per cent.
Small lymphocytes	90	"
Large lymphocytes	2.8	"
Mononculear	0.6	"
Eosinophiles	0.6	"
Myelocites	0.2	"
Mastcellen	0.2	"

EPICRISIS.

All four cases described as Hodgkin's disease were characterized by a large spleen, a moderate swelling of the liver, and enlargement of the glands. The last symptom was most pronounced in patient M. N. (Case IV.); in two of the patients (Cases II., III.) it was moderate, whereas in one case (Case I.) it was very slight.

Regarding diagnosis, there was no doubt that we had to deal with pseudoleukæmia or Hodgkin's disease. The tumor of the spleen alone (its long persistence, without involving other organs, its more or less hard consistency) and the result of the examination of the blood would be sufficient to establish the diagnosis. Besides we had swelling of the liver and glands and a protracted course of the disease.

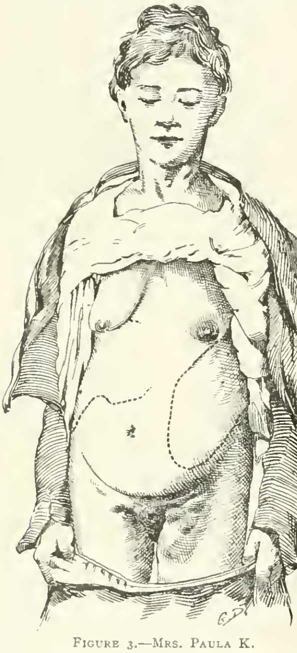

FIGURE 3.—MRS. PAULA K.
(Photograph, face changed.)

In three of these cases the stomach secretion has been examined; in two I always found a fairly normal secretion; HCl. present and the acidity varying between 40 and 50; in one case (Case III.) HCl. was present once; another time it was absent.

The intestinal functions were sluggish in two patients, and normal in one; in the fourth, however, diarrhœa was frequent. In two patients (I. F. and M. N.) an irritating dry cough was present, which is to be explained as being due in all probability to pressure of the mediastinal glands upon the bronchi. Fever was also noticed from time to time in two of the cases (I. F. and M. N.).

The two observations sketched under lymphatic leukæmia also hardly admit of any doubt in the diagnosis. Here, of course, the result of the blood examination was essential; added to this were the other characteristic symptoms. In one case (Paula K.) there was also cough present.

If we compare the cases of Hodgkin's disease described above with those of lymphatic leukæmia, we will find great points of resemblance between them. Especially marked is this in the case of M. N. (Hodgkin's disease) and the case of P. K. (lymphatic leukæmia). In both the symptoms of the disease were the same; the glandular swellings equally marked. Patient, M. N., really looks much paler than P. K., and yet we have to deal with leukæmia in the latter. The only difference lies in the blood. In the one the proportion of white to red is as 1 : 650, in the other as 1 : 32. The majority of white blood cells in case P. K. consists of lymphocytes, in Case M. N., however, the proportion of lymphocites to the other white blood cells is not above normal. In all the other cases of Hodgkin's disease the number of lymphocytes was not much increased. Only one case (I. F.) was an exception: here there was a slight increase of lymphocytes.

The difference in the condition of the blood seems to be great enough to enable us to separate the cases of Hodgkin's disease or pseudoleukæmia from those of true leukæmia, especially lymphatic leukæmia.

The opinion, formulated by Pinkus and others, that in pseudoleukæmia the relative number of lymphocytes to the other white blood cells must be increased, does not seem to me to be wholly in unison with my cases.

How is it that in spite of enlargement of the lymph glands the lymphocytes are not increased? As is well known, the lymph glands are looked upon as places of origin of the lymphocytes, and we would, naturally, expect an increase in them if we find the glands hypertrophied.

It is difficult to answer this question definitely. Just as in other glandular organs, when normal or even hypertrophied, there is sometimes diminished or totally arrested glandular activity (as, for instance, in the stomach), most, probably, due to nervous disturbances; so in the lymph glands there may be hypertrophy and yet no increased production of lymphocytes. We may, perhaps, assume that in consequence of the disease the energy of the lymph glands is expended upon their own development, and thus there is no increased formation of lymphocytes, to enter the blood.

Permit me to refer here, briefly, to the prognosis and treatment of the two conditions under discussion.

Prognosis.—The prognosis of lymphatic leukæmia, as well as of Hodgkin's disease, is decidedly bad. Both diseases end fatally; whereas, however, cases of Hodgkin's disease may extend over many years (four, five or more), chronic lymphatic leukæmia nearly always takes a more rapid course.

Treatment.—The therapy of both diseases is the same. We must pay attention to a suitable diet and a hygienic mode of life. The medicinal treatment is also of importance.

Regarding diet, large quantities of food must not be given at one time, and the food selected should be of a nature to leave little residue after digestion. This is done in order to prevent over-distention of the stomach or intestines. It will be best, therefore, to give about five meals a day, consisting principally of eggs, milk, gruels, some meat, little bread, much butter, and jellies. It is self-understood that in cases where the disease is not far advanced light vegetables and fruits, in small quantities, may be permitted.

Regarding hygiene, the patient ought to live in the the country, and much in the open air. Cold ablutions of the body, with subsequent brisk rubbing of the skin, will be of benefit.

Medicinally, arsenic occupies the first place; it acts almost as a specific, although complete cures are not obtained even under its use.

I usually prescribe simply Fowler's solution, starting with two to three drops three times daily and gradually increasing to ten or more, or we may give

℞	Acid arsenios	0.3
	Sodii. carbon	1.0
	Pulv. rad. liq	
	Succ liq	āā 5.0
	Glycerin	gtt. 11

F. Pil. N. 100. 2 to 6 pills daily.

Sodium cacodylate alone or in connection with iron has been of good service to me. I usually give:

℞	Sodii cacodyl	0.05
	Ferratin	0.5
	D. in caps. gelat. opert. t. d.	N. XX.

S: One capsule three times a day after meals.

Arsenic may also be used subcutaneously. Köbner[24] recommends the following mixture:

℞	Sodii. arsenios	0.1
	Cocain. mur.	0.03
	Aq. bis. dest	ad 10.0

M. D. Sterilisa,
0.5—2.0 to be injected daily.

Methylen blue, in doses of three or four grains, in gelatinous capsules, daily, may also be tried for a period of a few weeks. In some cases it seems to exert a temporary beneficial influence.

Recently, Pusey[25] found the action of the *x*-rays useful in diminishing the glandular swellings. I have myself had no experience with regard to the value of this agent in either Hodgkin's disease or lymphatic leukæmia. It certainly appears worthy of a trial.

THE TREATMENT OF PULMONARY INVALIDS IN FAVORABLE CLIMATES.

By EARL S. BULLOCK, M.D.,
SILVER CITY, NEW MEXICO.
MEDICAL DIRECTOR OF ST. JOSEPH'S SANATORIUM.

THERE has been a great deal said and written recently about the treatment of the tuberculous in so-called unfavorable climates; so much, in fact, that it is to be feared that the legitimate claims of a favorable climatic environment may be neglected. A point which I have sought in previous articles to impress is that, other things being equal, a pulmonary invalid has a much better prospect of recovery in a favorable climate. What is meant by the phrase "other things being equal" requires brief explanation. If, in the so-called arid region of the United States, a patient cannot receive as good care as at home, he should remain at home. Much unmerited reproach has been put upon the climate of this region because patients have been sent there insufficiently supplied with money, and, in consequence, subjected to hardships incompatible with recovery. As a result, I believe, of an imperfect understanding of conditions in the southwest, as well as of the requirements of the tuberculous invalid, patients are too frequently advised to go to the arid region who should never have been sent away from home. This is an expensive country in which to live. Supplies of all kinds come great distances and are correspondingly high in price. Opportunities for light employment, such as might be suitable for a consumptive, are practically absent. As the result of my experience with the invalid having an insufficient supply of money, I am convinced that great care should be exercised to prevent such people from going to a strange country, far from home. The result is almost always a dissappointment to the individual, and, occasionally, sad indeed. One hundred dollars per month, at least for the first year, is none too much.

Patients are commonly directed to go to El Paso, Silver City, or somewhere else, and "rough it," and keep away from physicians. In the minds of many physicians there seems to be an inbred prejudice in favor of "roughing it," yet nothing has been more clearly demonstrated than the need of rest and creature comforts for the tuberculous invalid. In avoiding physicians, as many patients do, they forfeit the privilege of learning what to do and what not to do. The majority of physicians throughout the arid region are themselves recovered "lungers," and, if they know nothing else understand the management of the tuberculous. Thus the patient, upon reaching the objective point, should seek a good physician and put himself absolutely into the hands of the doctor. Apart from professional services, *per se*, he will come into contact with an educated man, doubtless thoroughly familiar with the local conditions, who can aid in the problem presented by adaptation of means to ends. Under such conditions the patient is prepared to reap the benefit of a really ideal climate. And, let me repeat, the influence of a favorable climate in the treatment of the tuberculous has never been overestimated. It may be truly said that, of recent years, it has been rather the other way. In such a climate, when there is trust and obedience on the part of the patient, the treatment of the tuberculous becomes an actual pleasure, for, in incipient and afebrile cases, a clinical cure is practically certain; and, in those complicated by mixed infection, arrest and amelioration, if not cure, are frequently observed results.

The frame of mind exhibited by a patient is not, by any means, the least important element presented. In our institution here an effort is made to keep the tone one of cheerful hopefulness. In fact, the patients themselves resent any tendency upon the part of a newcomer to look upon the dark side of things. So important do I consider the psychic status in any given case that, if a patient persists in a pessimistic viewpoint, occasion is taken to have a talk, the purport of which is that "it might be better to go somewhere else." For without the cooperation of our patients, "in spirit and in truth," there is so little to be gained that the "game is hardly worth the candle." The psychic element in the treatment of the tuberculous is well illustrated by conditions at the Government Sanatorium at Fort Bayard. Patients are ordered there for treatment—the opportunity to get well is not sought, it is thrust upon them. The régime at Fort Bayard, from a scientific viewpoint, is above criticism, nevertheless, because the patients belong to a class who do not appreciate anything forced upon them, no matter how good the psychic state opposing rather than favoring recovery—the results will never be comparable to those obtained in an institution where the opposite state of mind prevails. In spite of this great disadvantage, the patients who have really appreciated the opportunity have been sufficiently numerous to demonstrate beyond cavil the superlative advantage of a favorable climatic environment in the application of the principles of modern phthisio-therapeutics.

What, in a practical sense, constitutes an ideal climate is always an interesting question, and one which may here be briefly discussed with profit. To my mind, the one absolute essential in a climate for the tuberculous invalid is such an average condition of weather and temperature as will enable him to remain *comfortably* out of doors the whole year round. Every other climatic feature is of secondary importance. Dryness, and its corollary, cloudless skies, deserve the next place. True, the *modus operandi* of a dry atmosphere is not fully understood, and the function of dryness rests partly, at least, upon empiric grounds; nevertheless, it is of established value. The explanation may be found in the fact that in a dry atmosphere patients are less susceptible to changes in temperature. It is well understood that the capacity of the air for retaining heat depends upon the amount of moisture it contains. This is exemplified by the suddenness with which it becomes cold in a dry region, as soon as the influence of the sun is removed, and with which it becomes warm as soon as the sun reappears. Thus, our nights are always really cold, and our days warm, even in winter. As all know, maximum dryness and sunshine are exceedingly inimical to bacterial life of all kinds and doubtless on this account play an important rôle in the treatment of both tuberculosis and phthisis, and, further, account for the fact that pure tuberculosis rarely becomes complicated by mixed infections in a climate presenting these features. It is a fact that regions characterized by dryness and unclouded skies are, in general, very healthful, which is illustrated by the hardiness of the native population of the southwest. The Mexicans are proverbially filthy, and, under less favorable climatic conditions, the death rate among them would doubtless be very high. It is an incontrovertible fact that the natives of the "arid zone" of the United States are practically free from tuberculosis. I have never observed a case. At Denver, Col., subtracting the alien tuberculosis, the death-rate is lower for this disease than in any other city of equal size in the world.

The characteristics of climate, which militate so strongly against bacterial life in general, doubtless explain why patients are so free from intercurrent affections—from colds to pneumonia. The records of the United States Sanatorium at Fort Bayard show that the patients there are practically free from such diseases. Of course, carefully regulated sanatorium life has much to do with the absence of intercurrent illnesses, but that alone, hardly serves to explain their almost complete absence. A region relatively free from the bacterial cause of disease should receive a goodly portion of the credit. For this, if for no other reason, it seems to me physicians are justified in sending their patients to such a climate; for it is manifestly to the advantage of the patient to be free from exposure to such affections as colds and influenza, if from nothing else. Tuberculous reinfection is hardly ever observed among our patients. The sunlight and the dryness of the atmosphere which kill other organisms are none the less fatal to the bacillus tuberculosis, and thus lessen the opportunity for reinfection.

Continued residence in a high climate usually causes emphysema, of varying degrees, even in persons who are apparently well, and in this lies the *raison d'être* for sending the tuberculous to regions affording this feature. In almost every favorable case emphysema becomes a factor within a very short time. An exaggerated percussion note is common even among healthy natives. Emphysema, in my opinion, directly blocks the progress of the tuberculous lesion. By resting the lungs, which it undoubtedly does, it is a truly conservative process and fulfills a most important therapeutic indication, common, not alone to this disease, but to the whole practice of modern medicine. I am aware that this doctrine is somewhat opposed to current opinion, but I am unable to interpret the action of empysema in any other way. Knopf of New York has demonstrated anew the usefulness of the pneumatic cabinet in hæmoptysis. A high climate, by lowering circulatory tension, and thus lessening pressure at the bleeding point, acts in practically the same way. Altitude both ameliorates and prevents pulmonary hemorrhages. At Fort Bayard (altitude, 6,040 feet) the records of the institution show the infrequency of hemorrhage and the mildness of its character when it does occur.

The effect of altitude upon the blood has been curiously misinterpreted, and, only recently, has become better understood. Much stress has been laid upon the sudden rise in erythrocytes which follows a change from a low to a high altitude. I have often recorded an erythrocyte count of 7.500 000 in a patient presenting the unmistakable clinical evidences of anæmia. This is now understood to be entirely a capillary phenomenon, and by no means indicates an actual increase in red cells.

Many writers furnish a long list of diseases in which the patient is said to be injuriously affected by high altitudes. As a result of a rather extensive experience, I believe that the contraindications of altitude have been much exaggerated. I would not send a patient to a high climate who had all he could do to keep alive from day to day in a low one; for altitude entails increasing passive exercise as one goes higher. Recent experiments have shown that oxygen absorption and carbonic acid gas elimination are increased directly in proportion to the altitude. Practically, advanced and febrile cases should not be sent to mountainous regions. As a rule, such patients do well nowhere, and I have known instances in which patients in advanced stages have died immediately on going to a high altitude. The statistics of the institution at Fort Bayard have exploded the teaching that hemorrhagic types should not be sent to high altitudes; in fact, have proved the contrary to be true; that high climates are especially adapted to this class.

As regards laryngeal cases, they are among the least favorable anywhere, and my opinion is that they do equally as well in high, dry localities as in low, moist ones. I have in mind several instances in which the patients are still alive after several years in high altitudes, and one in which complete recovery occurred after total destruction of the vocal cords. With the exception of advanced febrile cases, in which the extra work entailed by a residence in a high altitude is unquestionably inimical, all rules for sending patients to high climates fall to pieces. I have under observation, at present, a case complicated by severe mitral insufficiency, with imperfect compensation, as well as by a perirectal abscess, in which the improvement is little short of remarkable. One case, of course, is not sufficient to break an idol, but it is by no means the only one I have in mind. This patient does well, in spite of the classic teaching which would place his case in the list in which high altitude is contraindicated.

To sum up the features of an ideal climate, we may say that it should be warm enough to permit comfortable outdoor life all the year round, yet never so warm as to enervate. The atmosphere should be dry and the weather characterized by a maximum number of bright, sunshiny days. The altitude should be from 5,000 to 7,000 feet.

Where such a climate may be found is a question easy to answer in the United States. Portions of western Texas, eastern Colorado, New Mexico, and Arizona afford any modification of dry mountain climate that may be desired. Each place in the States and territories named has its particular climatic feature worthy of note: for instance, there is El Paso, with its glorious winters and enervating summer heat, and Colorado Springs, with truly perfect summers and somewhat too cold winters. Or the Silver city region, which, with an unsurpassed combination of climatic features, has the disadvantage of limited transportation facilities, and, in comparison with the other places mentioned, is unattractive indeed. In choosing a site for a sanatorium, I endeavored to find a region which embraced all the best features of a dry mountain climate, one which, taken the year round, would permit patients to remain out of doors with comfort and safety.

In selecting the Silver City region I was obliged to sacrifice many things which make other places attractive, but I am sure of the climate, which after all, is what people are sent west for. There are many places just as good, but most of them, in the present state of transportation facilities, are not so accessible to the pulmonary invalid. Speaking broadly, one can hardly make a mistake, as regards climate, in sending patients to any of the states or territories named. The patients themselves will usually drift to the particular spot that best suits them.

The mean annual temperature for the Silver City region is 54°F.; dew point, 29; relative humidity, 46, absolute humidity, 1.71 grains; rainfall, 12.3 inches; cloudy days, thirty-seven. These figures convey very little to the uninitiated in climatic lore, but, interpreted, mean that the region is characterized by warm winters—the result of the latitude, that of Savannah, Ga., and cool summers—caused by the altitude of 6,000 feet. The almost complete aridity of the region furnishes the best testimony as to the dryness of the atmosphere.

In a climate such as that just described the course of both pulmonary tuberculosis and phthisis is unquestionably modified for the better, even in the severe types of cases. Hemorrhages are infrequent and mild in character, even when they occur. Fifty per cent. of all cases are febrile upon arrival, but, as a rule, only a short rest is required to bring the temperature down to either normal or approximately so. But 14 per cent. are permanently febrile, and these are true cases of phithsis, in advanced stages. In them the daily maximum temperature is lower than in the same class in unfavorable climates, viz., 101°F. Night sweats are entirely confined to the febrile or mixed infection type, and, even among them, are infrequent and amenable to treatment. The diarrhœa of phthisis is practically unknown.

With an ideal climatic environment as a powerful therapeutic adjunct, the treatment of pulmonary tuberculosis becomes a matter of great simplicity. The principles which are now almost universally classic among phthisio-therapeutics—of constant rest in the open air, with forced nitrogenous feeding—should be applied as perfectly as possible, and the main usefulness of the physician lies in conveying to his patient a sympathetic cooperation in the application of these principles.

In the absence of specific medication of proved value, all attempts along this line are, in my opinion, both useless and unjustifiable. Medication consists of the intelligent application of drugs, for the purpose of alleviating symptoms and regulating functions. It is the business of the physician to take advantage of every point in the fight for health and life.

Cough, which does not accomplish expectoration, should be stopped by the use of codeine, which has proved itself, in my hands, to be the least harmful and most efficient of the series. To liquify viscid sputum, the use of carbonate of guaiacol, thiocoll and syrup of hypophosphites is often attended with happy results. A few days' rest in bed and small repeated doses of aromatic sulphuric acid are usually all that is required to control night sweats. For fever absolute rest is the only remedy that has proved efficient in my experience. Constipation, which is quite common among our patients, due, I believe, to the character of the drinking water, is best relieved by a saline before breakfast. Diarrhœa, which I have mentioned as extremely infrequent, yields perfectly within a few days if the diet is carefully regulated. Mild counter irrigation is usually sufficient to control pleurodynia. True pleurisy, in the majority of cases, is met by rest in bed and strapping of the chest. I have often been surprised by the quickness of the relief afforded in obstinate cases by an application of sterilized clay with antiseptics and glycerin. Anæmia, which is almost always present in newcomers, will correct itself in time, but the use of the various combinations of peptone, with manganese and iron, is usually attended by the acceleration of the return to a normal hæmoglobin index. The tendency to vomit after eating is often relieved by spraying the pharnyx with a 5 per cent. solution of antipyrine before meals, thus removing an excessive irritability, or, if vomiting still continues, it will be necessary to resort to measures directed to keeping the walls of the stomach clean, such as lavage or teaspoonful doses of phosphate of soda, dissolved in a glass of hot water, and taken half an hour before breakfast.

Anorexia usually disappears under forced feeding. The more work the stomach is called on to do, the more it will do, of course, within limits, and the amount of good food which can be handled is often surprising. I direct my patients to eat all they can, whether they want it or not, often bringing to bear the whole intellectual strength to the solution of the problem presented by an ordinary meal, and when it is impossible to eat more solid food, to swallow as much milk as possible. If they simply cannot eat, I direct that they receive the food as medicine, in small doses, at frequent intervals, and to accomplish this, it is sometimes necessary to fall back upon a liquid diet—principally milk

Faulty digestion is not often an element in a case. If patients can only be persuaded or made to take the necessary amount of food, they will usually digest it properly. In cases in which the digestion requires aid, lavage and dilute hydrochloric acid commonly meet the requirements, or, if the digestive fault is intestinal, taka-diastase is a powerful remedy. There is no drug that directly controls hæmoptysis, the new preparation, adrenalin having failed in my hands. Absolute rest, liquid diet and morphine, hypodermically, usually meet all requirements. In very severe hemorrhages, of which out of several hundred cases I have observed but two or three of this type; hypodermocylsis and tying off of the extremities are direct life-saving measures.

The principle of forced nitrogenous feeding, which underlies all dietetic measures, is a sheet-anchor in phthisio-therapeutics. Not only is it rational, but the results attending its application have been brilliant. Animals which feed extensively upon a meat diet are the least susceptible to tuberculosis—in fact, practically immune, the opposite being true of the herbivora. Among men, those whose daily diet is characterized by a preponderance of meat are relatively immune to tuberculosis. This is especially illustrated by the gouty, who, as we know, rarely contract tuberculosis. Therefore, we have every right to deduce the law that nitrogenous feeding is directly opposed to tuberculosis, and, in consequence, meat, milk and eggs form the rational basis of the consumptive's diet.

Alcohol, about the use of which in tuberculosis so much has been said and written, I believe to be fraught with greater danger to the patient than is justified by its questionable usefulness.

Gentle exercise, short of the point of fatigue, is always indicated in afebrile cases. On the other hand, exercise is absolutely contraindicated in any case in which the temperature is the least elevated.

What constitutes cure in pulmonary tuberculosis is an interesting question, and one which, I believe, cannot be answered, except in a relative sense. I have a firm conviction, however, that if a patient could be kept under proper conditions long enough the cure would be, to all practical intents and purposes, perfect. That one contracts tuberculosis at all is a fair evidence of an underlying constitutional defect—a weakness which implies susceptibility. If such defect be eradicated, it is accomplished only by years of carefully regulated living. This, to my mind, accounts, to a large extent, for the frequent relapses which occur in cases of patients returning east and being again subjected to the environment which originally caused the breakdown. Relapses are also partly accounted for by the fact that, no matter how perfect the cure may apparently be, there may still persist in the lung a tuberculosis deposit, which, at some future time, is capable of causing trouble. I formerly held that in the tuberculin test we had a perfect or relatively perfect criterion of cure. Even though convinced that the application of this test in men is justifiable, which I am not, I should still be obliged to doubt its efficiency; for I have seen a patient receive maximum doses of tuberculin without reaction, in whose sputum, within two weeks, bacilli tuberculosis were constantly present.

Clinically, when a patient has reached his average health and weight, and the bacilli have disappeared from the sputum, the patient is, for all practical purposes, cured. This by no means implies that a patient may return east with impunity, for my experience is all against leaving the climatic environment in which recovery has occurred. The rational thing to do is to make a new home in a new country.

As a matter of fact, we are often forced to let patients go out for themselves long before the bacillus disappears from the sputum. Actual necessity of earning one's living is the most frequently experienced cause of this, and, of course, one in the face of which both patient and physician are helpless. Under such conditions, even with the utmost possible circumspection as regards daily life, a cure is postponed, sometimes indefinitely. In a region where tuberculosis is not prone to develop into phthisis this is of relative unimportance. I know of several cases in which bacilli have been present ever since they have been known to science, and, during all these years, the patients have been doing hard work with no apparent detriment to general health. One can never tell beforehand how long it will be before bacilli will disappear from the sputum in any given case. I have seen cases in which an extensive lesion cleared within a few months; and, again, cases in which a small lesion remained absolutely unchanged during a number of years. Of one thing I am sure, and that is that the more perfect the application of the principles of rest in the open air and nitrogenous feeding, the shorter this period will be.

As regards the question of sanatorium *versus* home treatment, my experience is all in favor of the former. The success of home treatment depends entirely upon how completely it may be made to resemble that of the sanatorium. The conversion of a home into a sanatorium may be accomplished, under exceptional conditions, but only at greatly increased expense and by making every one about the house more or less uncomfortable. The sanatorium management has a definite purpose—to get patients well in the shortest possible time. Everything is conducted with that result in view. In a home, the proper conditions must first be created and then maintained, all at great expense and trouble to everyone concerned, and it is my experience that, after everything possible has been done, patients are rarely properly managed at home. There is always something going on which tempts a patient to do what he should not, which interferes with sleep, diet, and that perfect regularity so essential to recovery. The sanatorium is dominated by the spirit of getting people well. As all are managed alike, there is no incentive to commit indiscretions. If everyone goes to bed at nine o'clock there is no tempta- to remain up later. A rule of life which becomes irksome in the extreme, outside a sanatorium, is accepted without demur in a properly managed institution. Then, again, the complete breaking away from cares and trials, which, in the first instance have contributed to the loss of health, is not among the least of the advantages of sanatorium life.

What the consumptive should do when he recovers is a question which appeals directly to me, for it is one which I am frequently called upon to aid in solving. I am sure that the late pulmonary invalid should always live less strenuously than the majority of his fellowmen. The principles which contribute to recovery should, to a certain extent, dominate his after life, and should be modified only in so far as is essential in the adaptation to the problem of self-support. In aiding the consumptive to get well, we return him, as it were, to primitive conditions; we convert him into a meat-eating, out-of-door animal, and, in so far as is possible, such conditions should be maintained.

To remain in the country and climate which has helped to give one health is certainly a rational thing to do. It is recovered "lungers," like myself, who have thought and acted as I have indicated, who constitute so very largely the white population of the arid zone.

GYNECOLOGICAL ELECTROTHERAPEUTICS.

By BERNARD S. TALMEY, M.D.,
NEW YORK.

PATHOLOGIST TO MOTHERS' AND BABIES' HOSPITAL; INSTRUCTOR IN CLINICAL BACTERIOLOGY, NEW YORK SCHOOL OF CLINICAL MEDICINE; GYNECOLOGIST TO METROPOLITAN HOSPITAL AND DISPENSARY.

"PREJUDICE dies hard," says an old proverb. Every idea, every method encounters at its beginning convinced partisans and ardent opponents. Every therapeutical innovation that runs counter to prejudices and interests meets with opposition. Electricity has shared the same fate. Electricity, in any form, when applied to the cure of diseases, is set down as pure quackery by many medical men before it has had a fair trial at their hands. In nervous diseases, in which surgery is impotent, some place was acceded to electrical treatment, but in the rapid strides which gynecological surgery has recently made, electricity has taken but a small part. Here it is lauded as a curative agent by some, derided and denounced by others, and looked upon with indifference by the mass of the profession. Yet the gynecologist has continually to deal with the intimate relation of the nervous system with the genital sphere, and electricity celebrates its triumphs mainly in its relation to muscle and nerves. It ought, therefore, to have an honorable place in gynecological treatment. Yet surgery overshadows this slower method, and many a gynecologist acknowledges nothing but the knife as the savior of womankind. The operative craze has gone on growing and growing up to the present day, until it has become a very serious matter for a woman to consult a gynecologist, for fear that the verdict may be "out with your ovaries and uterus." Women are daily put under the perils of castration and hysterectomy, and the abdomen of every woman having an undue sensitiveness of the adnexa is opened either for exploration or castration. The exploits of laparatomists have given a new character of boldness to abdominal surgery, yet surgery does not always cure, and should frequently be set aside for a safer measure. We are bound by professional morality to make trials of every system of treatment in every case before we recommend mutilation. The patient should first have the benefit of an electrical treatment, which statistics have shown to be of great value in many genital diseases. We should give to this method of treatment a proper and thorough trial before rushing the afflicted patient to the operating room, there to undergo the dangers of the knife. We must protest against indiscriminate and needless operations, and should not continue to hold electrical treatment in abeyance.

To be sure, the physician who wishes to apply electricity in the treatment of his patients not only should be well-versed in the general science of electricity, but should also know the effect the electric current has upon organic matter.

The varying qualities of the electric current as applied to inorganic matter are best known. The physical effects are, in the first place, the transfer of substances from one pole to the other—oxygen is generated at the positive pole and hydrogen at the negative pole—then the regulation of endosmose and exosmose, and finally the production of heat, which is proportional to the resistance[1] and the square of intensity[2] $Q = E \times I$. Similar are the effects of the current traversing animal tissue. The positive pole attracts the acids, and is therefore coagulating, styptic, caustic and hemostatic; the negative pole attracts the alkalies and is liquefying, electrolytic, and, in a certain degree, caustic.

The anatomical examination of the interpolar tissues traversed by an intense current of electricity shows evidence of molecular disintegration. The current interferes with the nutrition, the vessels shrink, the form changes, and the substance contracts. An excess of temperature of about 50°C is generated at the positive pole by a current of 200-250 milliampères. The heart of a dog was exposed to a current of 40 M., and it was found that in the part from the direct line of the current the striæ had become granular, in the other part the muscle cells remained unchanged.

The physiological effects of the electric current take place only by virtue of the vital properties of the body through its action on the nerve supply, influence upon the circulation, secretory and excretory processes, and the acceleration of the absorption of morbid products. Hence, when the current passes through living tissues the interpolar action of the positive pole is, by contracting the capillaries, anodyne, sedative, anticonsestive, denutritive, and antihemorrhagic, the interpolar action of the negative pole is, by increasing the blood supply, stimulating, consestive, derivative, and alterative, favoring absorption. No animal tissue whatever, says Althus, can resist the disintegrating effect of the negative pole, and the form and rapidity wherewith this disintegration is brought about are directly proportional to the electro-motive force which is employed, and to the softness and vascularity of the structures acted upon. The action of the negative pole is a double one. The negative electrolytic decomposition of animal substance or liquids gives rise to an evolution of bubbles of hydrogen that mechanically affect the tissue near the pole by insinuating themselves between the structural elements and driving their fibers asunder. This is a point established by microscopical observation. The second effect is a chemical one caused by the alkalis. Soda, potash, lime with hydrogen, are liberated by decomposition of the animal matter and go to the negative pole. The polarization that takes place in the organic tissue when the continued current passes through the animal body not only acts primarily but also has an after effect. The acids having gathered at the point of the entry of the current and the bases at the point of exit, the negative eschars are, therefore, softer and moister. Thus the physical and physiological polar and intrapolar properties of the galvanic current are as follows:

---

[1] Ohm is the resistance offered to an electric current by a column of mercury 1.06 meter long to 1 millimeter square. Volt is the electromotor force equal to about one Daniel element. Ampère is the intensity of a current of one volt passing through one ohm.

[2] $Q =$ quality of heat. $E =$ electromotor force. $I =$ intensity. $Q = E \times I$.

The positive pole generates oxygen, attracts acids, is coagulating, styptic, caustic, hemostatic, anodyne, sedative, anticongestive, and denutritive.

The negative pole generates hydrogen, attracts alkalis, is liquefying, electrolytic, caustic, stimulating, derivative, alterative, favoring absorption, and increasing the blood supply.

The physiological effects of the faradic current are mainly mechanical. We obtain a veritable interstitial massage. It calms, therefore, the nerve system, diminishes excitability and relieves pain, especially with the fine coil. The coarse is only used for muscular contractions. By its power over muscular contractions faradization sensibly increases temperature.

The physiological and anatomical properties of electricity have long since shown its value as a curative agent in gynecology. Various attempts have from time to time been made to introduce electricity into the treatment of uterine diseases, and its aid in a great diversity of methods of applications was invoked long ago. But while the old method only utilized the radiating effect of the interpolar properties and the currents were used empirically at random, we have in Apostoli's method strict indications, differentiation between galvanic and faradic currents, differentiation between the positive and the negative pole, localization and concentration, precision in dose, strong currents and short sittings, and appropriate apparatus. The only treatment, says Keith, worth speaking about that is helpful and which at the same time is free from danger to life—if the treatment be undertaken by one who has respect for a strong electrical current—is that brought before us by Apostoli. It is not a method to be applied indiscriminately, but it has opened a delightful study, which increases in interest every day the closer we study it. This method should, therefore, take precedence over all others. We have in it a combination of intrapolar electrolysis and of galvano-cauterization of the mucous membrane.

The main principles enunciated by Apostoli are the introduction of the active electrode into the uterine cavity and the employment of high dosage. Before Apostoli about 20 milliampères was the highest dose. Apostoli used from 50–250. Now, the galvanic applications, says Gautier, have a therapeutical effect, which is proportional to the square of their energy. Another difference brought by Apostoli's methods is that while formerly the uterine cavity was a *noli me tangere* and the active electrode went no farther than the vagina, Apostoli has taught us to go as near as possible to the seat of the disease.

These two changes required some modifications in the apparatus. Any battery with an electromotive force of fifty volts will serve the purpose, if provided with a rheostat to avoid the shock, when employing high intensity, and a galvanometer to regulate the dosage. The innovations of Apostoli are the introduction of electrodes of platinum and carbon for the active positive pole, to avoid erosions by the acids. For the inactive pole at the abdomen he introduced the clay-pad, to avoid cauterization. The resistance offered by those parts with the clay-electrode is less than 200 ohms[1] for electricity takes the most direct route to complete the circuit.

The diseases amenable to electrical treatment are, according to the physiological properties, manifold. The interpolar action of the current has been made use of for the progressive stoppage of the hemorrhage and relief of the uterine congestion and the mitigation of ovarian neuralgia. The faradic current is used by reason of its contraction of the musculer fibers, in subinvolution, infantile uterus, post-partum hemorrhages, amenorrhœa, sterility, and chronic metritis. The anticongestive action of the positive pole is of value in metritis, endometritis and hemorrhages. Apostoli used it also for its microcidal properties. The denutritive action of the negative pole is made use of mainly in fibroids, where it causes the anatomical diminution cessation of hemorrhage, disappearance of all symptoms of compression, and the symptomatic restoration of the patient. It is also used in dysmenorrhœa caused by stricture of the internal orifice. The galvanic current is a sovereign remedy for the painful and circulatory troubles, as amenorrhœa, it aids the resorption of primitive exudations, and its calorific action causes a circulatory drainage of the internal genitals, and is of great benefit in salpingitis and ovaritis.

Thus the fascinating and attracting electrical fluid has been tried in almost every pelvic trouble, making it a proper medium for the charlatan. Yet it cannot always be used with impunity. There are strict contraindications. Every suppuration in the pelvis contraindicates electrical treatment. When febrile excitement arises all treatment is to be suspended. Suppuration in the neighborhood of a fibroid or cystic degeneration of the tumor is a contraindication to the local employment of electricity, and every liquid collection, uterine or perimetric, contraindicates absolutely the high intensities.

The exact diagnosis is, therefore, one of the prime necessities before any electrical treatment may be tried. But the diagnosis once established, electricity can and has been used with safety and the best results by the greatest authorities.

Keith, than whom there has seldom been a closer and more accurate observer, found out of seven cases of fibroids treated by electricity that five had entirely disappeared. He attributes the diminution to electrical osmosis. The patients thus treated, says Keith, are satisfied with the efforts made to save them from the operation that jeopardizes their lives and leaves them with a mutilation abhor-

---

[1] Ohm's law: $C = \frac{E}{R}$

E = electromotive force. C = current in ampères. R = resistance.

Thus the current of 50 volts divided by 200 ohms is 250 milliampères, or ¼ of an ampère rent to a woman, and, furthermore, often fails to cure her. In another paper Keith says his confidence in curing many chronic inflammatory conditions in the pelvis continues to increase. Lawson Tait says the electrical treatment must be tried no matter what difficulties may be encountered with the task. Apostoli had the best results with his electric medication of fibroid, endometritis, ovariosalpingitis catarrhs and perimetric phegmosis. For metritis he found the bipolar intrauterine faradization the best application, because it is much easier, less painful, more active, and more efficacious than the former subpelvic-abdomino-uterine or recto-uterine applications. Goelet found that with 200 milliampères exudates and adhesions melt away like ice under the sun. Bröse says electrical application is indicated in myomata, exudates, metritis, endometritis, but only after every acute or subacute inflammation has entirely disappeared. MacGinnis considers electricity the best agent in the treatment of rebellious cases of old parametritis, in cases of sterility due to the inactivity of uterus, when the ovaries are otherwise perfectly well, and in the appeasement of inflammation in cases of simple ovaritis. Smith used bipolar faradization in subinvolution, post-partum hemorrhage, deformity and defacements of the uterus, ovarian pain, vaginismus, and abdominal pain due to hysteria. He further treated 200 cases of fibroid tumors with the galvanic current with satisfactory results. He used the vaginal ball electrode covered with moistened cotton of the negative pole in all chronic inflammatory exudations in the pelvis. Massey says, in simple endometritis galvanic currents locally are practically infallible; he has never seen a case resist them. In another paper he mentions thirty cases of fibroid tumors treated at the Howard Hospital in Philadelphia. In all but one there was a symptomatic cure with or without reduction in size. Of sixteen cases of chronic metritis thirteen were cured and two improved; of fourteen cases of perimetric inflammation six were cured and six improved; of four cases of chronic ovaritis two were cured and two improved; of seven cases of subinvolution all were cured; of five cases of menorrhagia four were cured and one improved; and of four cases of endometritis three were cured and one improved. Baker has employed electrolysis in the treatment of fibroid tumors in fourteen cases with highly satisfactory results. Engelman found, in prolapsus uteri, due to relaxation of tissue, the judicious use of the electric current to be of the greatest value, at the same time affording perfect immunity from pain. Webb found faradization of the uterus the best palliative remedy. He used the negative pole to control the growth of fibroid tumors, and saw pain assuaged, bleeding stayed, countenance brightened, and appetite returning. Ford says: "I have been surprised to find a number of cases of ten years' standing in which there has been no increase in the size of the fibroid." Rockwell relates a case of severe ovarian pain that required the removal of both ovaries, but the pain continued even after the menses disappeared. Under internal application of the galvanic current, varying from 25 to 50 M., the paroxysms began to yield rapidly, resulting in a few months in a complete recovery. He asks whether it was necessary to perform the formidable operation. Sanders found that medical measures alone against chronic oophoritis are almost valueless, and the results of thirty-one cases of oophorectomy afterward examined were not flattering to the operator. Pain continued in twenty-four of these cases, while electricity succeeds fully in 90 per cent. Pain and the other distressing symptoms of the disease vanish. Even Labardie Lagrave, not a great enthusiast as regards Apostoli's method says the observations of Massey, Smith, Snenireff, Delétang, La Tore, Spencer Wells, and Playfair are all of the same accord to prove the good and often rapid results of intrauterine electrization. Grandin, who recently answered the question: "Has electricity ceased to be a useful therapeutic agent in gynecology?" in the affirmative, has himself treated four to six patients with ectropic gestation by electricity, and all of them recovered. But, he says, who can tell whether there really was ectropic gestation since the abdomen was not opened. This question is somewhat queer. Who can assure the correctness of the diagnosis in a cured case of pneumonia? Surely an exploratory laparatomy will clear up any doubtful diagnosis of the diseases of the pelvic organs. But the value of exploratory operations, says Russell, is merely as a cloak for want of diagnostic skill.

Yet deprecatory remarks have been made against electrical treatment. First among the doings pointed out was the danger of the utilized high intensities, then the danger lying in the intrauterine applications and the danger in the intrauterine caustic action. To these objections Apostoli answers with the following advice: No higher intensity than tolerable to the uterus should be applied. The patients should never be surprised and pained. The maximum dose should be arrived at progressively and decreased in the same way. These precautions do away with all the dangers. Its failure in a great many pelvic disorders has been further urged against electricity. But there are conditions that are also incurable by any other method of treatment. Another objection to electricity was that no explanation for its action is obtained, but the why and wherefore of things matters little for our purpose. There is no explanation for the retrogression of fibroids and uterine tissue after the menopause either,the good results attained are all that is necessary. It was my good fortune to witness the work done in Apostoli's clinic in Paris, and to see the good results realized. Surely I would not claim for electricity that it has displaced every other variety of treatment. We must avoid, says Gautier, the two extreme tendencies, the exaggerated enthusiasm and the too severe scepticism. But before every extirpation of ovaries and uterus we have to think twice of the dangers of life and the after effects that entail much suffering, as artificial menopause, intestinal obstruction, abdominal hernia, fistulæ and adhesions, and last, but not least, the mental suffering caused by the not infrequent destruction of the sexual sense. Castration, therefore, which morally or physically mutilates a woman, should be regarded as a last resort. To be sure, the electrical treatment is not an easy task; conditions may arrive at each step and demand great vigilance; it requires much thought and an exact diagnosis is an indispensable requirement, otherwise fatal consequences are the result. But we must insist upon the importance of an accurate diagnosis before commencing any treatment, even laporatomy. It has been claimed against electricity that it does not effect an anatomical cure. But does surgery effect one? The amputation of a gangrenous leg saves life and relieves suffering. But does it bring an anatomical cure? Has the gangrenous leg been restored to health, or has not the patient rather been crippled? Is not a woman deprived of her ovaries or uterus also crippled? Where does the anatomical cure come in? Major surgery never brings a restitutio ad integrum. But why cavil about the importance of anatomical cure, the symptomatic cure concerns the patient most. What brings women to the consultation room is that they have pains, discharge, or hemorrhage. If these symptoms are removed the patient may be considered cured, at least as far as she is concerned. Then surgery does not always even cure symptomatically. Many cases are reported cured when they are simply relieved from the immediate effect of the disorder, and when, in fact, they are in worse health than before the operation. The women who suffer ill-health after losing ovaries and uterus are legion, and the records of surgical treatment, says Skene, are not very largely in the interest of patients,though they may be in the interest of surgeons. To subject a patient, says Sanders, to the risk of losing her life by operation when life is not endangered by the disease itself, is not right either in logic or in ethics. Lusk says: The more the question is studied, the more clear it becomes that the loss of her ovaries does make a difference to a woman. Castration consigns a woman to a future of sterility, causing her irreparable physical and moral shock. The ovaries have besides that of ovulation, some important function in metabolism to perform. Besides, every time the abdomen is opened, says Apostoli, there is a question of life and death, and it should be resorted to only after electricity has failed, for if ever a remedy had physiological and anatomical reasons for its application it is electricity.

6 WEST 123D STREET, NEW YORK.

Cholera in Borneo.—It is reported in the London press that cholera is raging among the native troops of Sarawak in British Borneo. They were sent in boats up a river on an expedition against a band of head hunters and the disease soon appeared among them, decimating them. The outbreak was attributed to the drinking of infected river water. The disease is reported to be spreading among the natives living on the banks of the river below the point where the troops were attacked.

MALARIA AS A COMPLICATING FACTOR IN THE DIAGNOSIS OF APPENDICITIS.

BY HENRY J. WOLF, M.D.,
NEW YORK.

THE sudden development of grave symptoms, eventually recognized as malarial, in the course of various abdominal affections has at times given rise to the gravest apprehensions as to the ultimate outcome, obscured or rendered impossible the clear understanding of a case, or even suggested the necessity of surgical interference. Thus malaria, complicating a comparatively innocent attack of gallstone colic, has simulated empyema of the gallbladder, or even hepatic abscess, has suggested the possibility of surgical complications of the affected organ in the colic of renal calculus and in cases of floating kidney with twisted pedicle, has appeared post-partum in the guise of puerperal sepsis to be detected only *ex juvantibus*, and, finally, has imposed the question of further surgical interference, or of revision of the abdominal wound, by its sudden development after major operations.

The complicating element which may thus affect prognosis, diagnosis, and theraphy, is especially misleading when positive anamnestic data of previous chills and fever are wanting, when a close study of the blood fails to reveal plasmodia, or reveals them only after repeated examinations, when the spleen is but slightly, if at all, enlarged, or when its size cannot be determined to our satisfaction by the usual physical methods, when the course of the fever is not characteristic or is directly misleading, *e. g.* the double quotidian type, and, finally, when the malaria does not respond to quinine.

After the malarial element has once been recognized, we are, to a certain extent, on the lookout for its reappearance as a complication in subsequent attacks of the primary affection, and the diagnosis becomes comparatively easy.

Important and interesting as the study of this class of cases has been, it would be foreign to the purpose of this paper to go into detailed descriptions of the errors which have obtained even in spite of the united efforts of men of wide experience and recognized ability. Such errors will continue to be made as long as we are unable to make a positive diagnosis of malaria in every case, while, on the other hand, the presence of malaria, however definitely established, by no means excludes the coexistence of a condition which it frequently simulates. Such conditions as those just described are not merely possibilities, nor are the surgical complications alluded to very rare in large districts where malaria abounds.

These general considerations apply with particular force to affections of the vermiform appendix, which also seem capable of awakening long dormant or unsuspected malaria. Nowhere, however, is the earliest recognition of the malarial intercurrence of more vital importance than here, for the diagnosis "appendicitis" may carry with it the indication for immediate surgical interference. The onset of a chill and fever due to unsuspected malaria would subject the patient to an untimely operation, and both physician and surgeon would commit a diagnositic blunder, unless, as may well happen, the grave general symptoms are actually due not only to malaria, but to the diseased appendix as well. Their association, from time to time, will not be surprising in large centers like New York City and its malarial environs, where each of these affections is of such frequent occurrence.

It would be well to consider with especial care the possibility of malaria in cases where the ileocæcal symptoms, pain, tenderness, rigidity of rectus, are mild or on the wane, and do not harmonize with the gravity of the general manifestations, chill, rapid pulse, increasing temperature, and serious appearance of the patient. Still we must ever bear in mind how little we know of what is going on in a crippled appendix, and remember that a lull in the symptoms is at times only an unhappy dividing line between two totally different aspects of the same case. The time consumed in examinations for plasmodia may afford a breathing spell, when an abatement of the more serious symptoms incidental to the sudden malarial invasion may be noted.

To interpret sudden synchronous malarial and ileocæcal symptoms correctly, some caution is necessary, for malaria, like other acute infectious diseases, has frequently, in my own and other physicians' experience, simulated appendicitis.

Type of Malaria Simulating Appendicitis.—Mrs. M. H., forty-three years of age, healthy, not aware of previous malaria, became suddenly seized with a chill, and was doubled up with very severe abdominal pain, which was referred to the appendix. Vomited repeatedly. On examination, tenderness, which, however, was uninfluenced by pressure, was found in the region of the appendix. Pulse over 120; temperature, 106°. In this case, the hyperpyrexia practically excluded the appendix as its cause. It did not, however, exclude the possibility of coexistent appendicitis. What made the latter diagnosis improbable was the fact that local pressure did not increase the ileocæcal distress, and that a suitable antipyretic in time relieved all regionary symptoms. Plasmodia established the malaria. The diagnosis of this and a number of similar cases in which the malaria was not so readily suspected on account of the absence of chill, or because the temperature at the time of observation was very much lower, is apparently very simple at a distance from the bedside; confronted with the situation, however, some worrisome moments are apt to ensue. This has been noted, perhaps, more particularly in younger children, in whom abdominal examinations prove very often anything but satisfactory.

Type of Malaria Coexisting with Appendicitis.—Louis G., fourteen years of age, unusually well and strong. Never, during a nine years' acquaintanceship, suspected of having malaria. November 20, 1901: While at school, seized suddenly with cramps and vomiting. On examination tenderness was found in customary region, but nearer to spina superior ilei; some rectus resistance. Pulse, 76; rectal temperature, 100°; spleen small. Diagnosis: Appendicitis. November 21, A. M.: Pain and tenderness totally disappeared; slight ileocæcal sensitiveness only on very deep inspiration. Pulse, 72; rectal temperature, 99°. Toward evening seized suddenly with chill, lasting ten minutes; pulse, 90; temperature, 102°. No pain or ileocæcal tenderness. In right tonsil a follicular spot was found which occasioned no discomfort; spleen enlarged. These symptoms, with the initial ileocæcal manifestations, suggested the possibility of a typhoid infection. November 22, A.M.: Tonsillar spot disappeared, spleen larger, rectal temperature, 97° (without antipyretics). Typhoid then excluded. Appendix still far from all symptoms. Quinine then administered. Chill did not ensue that evening; temperature, 101°. November 23, A. M.: Rectal temperature, 97°; quinine continued Evening temperature, 99°. Hand in hand with convalescence, a decrease in size of spleen was noted. Quinine continued one week. Patient remained well in all respects until just one month later. Diagnosis: Malaria, and malaria simulating or possibly obscuring appendicitis. December 22, 1901: Suddenly, while in bed, seized with pains in pit of stomach, with nausea. After lapse of a few hours pains descended to the right side of abdomen. December 23, 1901, A. M.: First examination: Tenderness over same spot as during first attack, increased on pressure; rectus muscle slightly rigid; nausea. Rectal temperature, $98\frac{3}{5}$°; pulse, 72. Spleen small. Diagnosis appendicitis. Five P. M., status idem; 10 P. M., occasional dose of morphine had to be given to control colicky pains. December 24, 1901, A. M.: Chill of ten minutes' duration. Pulse, 106; rectal temperature, 102°. Spleen appeared still normal in size Eleven A. M., general appearance of patient grave; pains persist, though not quite so intense as in the beginning.

My experience of the previous month urged me to wait and look for a repetition of similar events. Judging the attack by itself, however, the chill and other graver symptoms would certainly have indicated immediate operation. Four P. M., five hours later, patient appeared very much more comfortable. Appendix tenderness though present, very much decreased; rectus reflex absent; pulse, 120; temperature, 103°. In view of the amelioration of the ileocæcal symptoms, the chill, rapid pulse, etc., were regarded, as in the foregoing attack, as symptoms of the malaria, and not of the diseased appendix. The report of the blood examination was then positive for plasmodia, and the patient, under the usual régime, recovered, with slight tenderness persisting over the appendix until its removal by Dr. Willy Meyer, January 2, 1902.

Macroscopical Examination of Appendix.—Organ, found where clinically located, was very long and adherent at tip; adhesions fresh and easily detached, bleeding freely; constriction visible externally at lower third of organ, from constriction to tip: appendix thicker, dark, coppery red; centrally from constriction, appendix apperared normal in size and color. Corresponding to constriction, an obstacle encountered on attempting to pass probe. Lumen of appendix contained fecal matter either side of stricture, from which centrally the mucosa and muscularis appeared normal in thickness and color, distally the mucosa was dark, coppery red, very much thicker, as was also the muscularis and serosa.

In the cure described the situation was not very clear from the beginning. It was only on the occasion of a second attack, just one month after the first, that the events of the latter became intelligible to me. Without the experience of the first attack, however, I should, in all probabilities, have failed to recognize the significance of the chill, rapid pulse, higher temperature, and graver appearance of the patient, and should have advised the immediate removal of the appendix. Were my doubts as to the correctness of the diagnosis "appendicitis" during the first attack justifiable in view of its subsequent developments, which, in spite of no examination for plasmodia, could reasonably be interpreted as malaria? The comparatively short duration of the ileocæcal symptoms would not of itself militate against the diagnosis "appendicitis," but when associated with pronounced malarial manifestations which can, and not infrequently do, simulate appendicitis, uncertainty becomes inevitable.

The second attack cleared up the situation. Without any suggestion from me, the patient described his pains as having begun suddenly in the pit of the stomach, having been attended with nausea, and having descended after the lapse of a few hours to the right side of the abdomen, a description so pathognomonic of appendicitis. The tender spot near the anterior spine was found identical in location with that of the first attack. This spot remained more or less tender until the removal of the appendix, when there were no more symptoms of malaria apparent. Thus the diagnosis appendicitis was established and the ileocæcal symptoms of the first attack were, by inference, similarly construed. Plasmodia verified the diagnosis of malaria, in the second attack, and, we may safely infer, in the first attack likewise. We can, furthermore, conclude that the chill and graver symptoms of the second attack were, like in the first, malarial manifestations, occurring as they did, when the ileocæcal symptoms were, if only slightly, on the wane.

The diagnostic difficulties in the combined affections would be still greater if the grave symptoms repeatedly mentioned were referable to the appendix. In such an event a rapidly acting antipyretic might shed some light by depressing the temperature, which, however, might not be associated with a corresponding decline in pulse rate, and marked alleviation of other symptoms. In this case immediate surgical intervention would be indicated.

Clinical Department.

ACUTE PNEUMATOSIS GASTRO-INTESTINALIS.

By E. CASTELLI, M.D.,
WASHINGTON, D. C.

Under this title I intend to differentiate an acute symptom of dyspepsia from the usual symptomatology of acute indigestion. I think the differentiation necessary not only in a scholastic point of view, but principally on account of the treatment. I want to point out that there exists a form of acute indigestion due to the presence of undigested food in the stomach and another form due to the rapid formation of gas in the stomach and intestines not always connected with the indigestion of food. Those two forms present themselves in the same way, and we treat them under the same circumstances; *i. e.* we are called in a hurry to assist a patient in a comatose state, surrounded by anxious relations and friends. But it is in these cases that the diagnosis must be made *cum grano salis* if we want to save the life of the patient. If the attack is due to the presence of undigested food in the stomach, it is important, of course, to remove the abnormal matters by emetics, but if it is only due to gas, or to gas and food, the treatment must be different.

What is the pathogenesis of *acute pneumatosis gastro-intestinalis?* The pneumatosis must be considered as of nervous origin. The nervous system manifests its action not only on the secretion and composition of the gastric juice favoring the decomposition of food in the stomach but also on its hyperactivity, which may give rise to a true secretion of gas analogous to that observed in hysterical persons. Such a secretion occurs sometimes suddenly, producing a rapid distension of the stomach and intestine, and gives rise to the same symptoms as acute indigestion. I think such form of indigestion more serious than the others if not properly diagnosed. We often hear of patients treated for an attack of acute indigestion, in whom the doctor had diagnosed no serious symptoms, dying suddenly—what does that mean? It means that the emetic had relieved for the time being all symptoms of hyperdistension produced by the gas, but that a new and sudden production of gas had caused death.

I have lately had two cases of pneumatosis gastro-intestinalis. One of these is herewith related:

A prominent lawyer came to Washington a few days ago on a very important business matter. His ambition, the responsibility of the case, and all the circumstances connected with its successful termination had made him very nervous. During the last two days he had no sleep at all and he had taken little food. Owing to constipation and lack of appetite, he had taken a few grains of calomel. In the evening of the 21st, before going to dinner, he suddenly felt dizzy and had just time to reach a sofa when he became unconscious. I was called immediately. I found the patient in a comatose condition. His breathing was stertorous, the skin dry, the pupil dilated, and the pulse filiform. I had seen the patient before and I knew of his general good condition. The wife informed me that the patient had had his last meal at lunch time, consisting of a poached egg and a piece of the white meat of a chicken. In the last twenty minutes the patient had had a sensation of fulness in his stomach and eructations of odorless gas. I had the patient undressed at once. His abdominal wall was overdistended and a tympanic skodic sound was detected all over by percussion. On pressure on the abdomen odorless gas was emitted by the mouth. I diagnosed *acute pneumatosis gastro-intestinalis.*

Treatment.—Application of a hot pack on the head and inhalations of a few drops of amylnitrite, dropped on a handkerchief, with the object of increasing the respiratory activity.

My opinion of the cause of death in patients during a gastric attack is that death is due to a toxæmia affecting the *respiratory center* and not to heart failure, as so many believe. For that reason I think it rational in such cases to act rapidly on the respiration and only secondarily on the heart.

In the meantime I proceed to the systematic massage of the abdominal walls, with the object of removing the surplus gas that causes the alarming symptoms.

I should call this my emergency treatment.

With the amylnitrite and the massage the patient usually returns to consciousness and the respiration becomes normal.

The second step in my treatment is to remove completely the gas and the cause of it; *i. e.* the nervous condition that precedes its production. For that purpose I administer every half hour the following solution:

Elixir paraldehidum	16 grammes.
Ether sulph	10 drops.
Aquæ anisi	40 grammes.

and continue the massage. After the administration of the fourth or fifth dose the gas generally disappears, the patient feels easy and drowsy. Should the patient wake up during the night I repeat the same dose. Generally within twenty-four hours the patient returns to his primary conditions.

Further Treatment.—I prescribe a few days rest from business, distraction, nourishing food, and small doses of one or other of the bromides.

New York, July 12, 1902.

THE INTERCOMMUNICABILITY OF HUMAN AND BOVINE TUBERCULOSIS.

ONE of the most effective arraignments of Professor Koch's injudicious speech, with regard to the connection between tuberculosis as affecting cattle and the human race, was made by Dr. Adami, Professor of Pathology, McGill University, Montreal, and published in a recent issue ot the *Medical Chronicle.*

Professor Adami, at the Congress on Tuberculosis, recently held in New York. brought out the same points as in the article mentioned.

His conclusions were as follows:

1. Bovine tuberculosis is easily conveyed from cattle to cattle and whether by inhalation, by the milk, by contamination of stalls and drinking water, through the agency of the saliva and nasal discharge, through the genitourinary passages, or by intrauterine infection. this transmission from one animal of the bovine species to another is far and away the commonest mode of infection in cattle, so common that for practical purposes all other modes may be neglected.

2. Human tuberculosis is transmissible to cattle. Pure cultures of the bacilli rarely cause infection. Mixtures of tubercle bacilli, with other micro-organisms (as in sputum) appear to be more infectious. The difficulty in inducing artificial tuberculosis favors the idea that natural infection of cattle with human tubercle bacilli must be of singularly rare occurrence.

3. Certain breeds of swine appear to be easily infected with both human and bovine tubercle bacilli. and when infected with the former, these gain an increased virulence for guinea-pigs and rabbits. But while through the use of infected milk, these animals frequently become infected from cattle. conditions favoring the reverse process are rare. Thus, while it may occasionally be that some, or possibly other domestic animals, act as intermediaries in the passage of tuberculosis from human beings to cattle, the conditions favoring such transmission from man to hog, from hog to cattle, so rarely show themselves that, again, for practical purposes, this mode of infection may be neglected.

4. If this be so, it should be possible to eradicate bovine tuberculosis in a region in which human tuberculosis continues to be widespread.

5. Human tuberculosis in the majority of cases is conveyed from human being to human being by inhalation, more rarely it is conveyed through the alimentary canal, still more rarely through the genital tract, through surface wounds, and from the mother to the fœtus during intrauterine life.

6. Everything points to the fact that in the main the bacilli are derived from previous cases of the disease in man.

7. By sojourn in the human body and passage from man to man, the human tubercle bacilli have acquired properties different from those acquired by bacilli which have passed through cattle. Their shape differs, the rate of growth and the appearance of the growths outside the body are different, and their virulence toward the animals of the laboratory is also different.

8. These differences are not, however, sufficiently marked or constant enough to permit us to conclude that we are dealing with distinct species; on the contrary, the evidence at our disposal points clearly to the fact that in the different species of animals we encounter, at most, races of tubercle bacilli, which, by growth in the bodies of animals of another species take on the characteristics of the race of baccilli peculiar to that species.

9. Bovine tuberculosis can be transmitted to man, and this either through wounds or through the digestive tract.

10. By passage through cattle the tubercle bacilli gain increased virulence for cattle, rabbits, and guinea-pigs, but lessened virulence for man and, it would seem, also for carnivorous animals.

11. Save in the very rare cases of wound infection, there is a significant lack of evidence that bovine tubercle bacilli infect adult human beings.

12. It is infants and those of early age who are liable to be infected by the tubercle bacilli of bovine origin, and this through the agency of milk. The statistics bearing upon the continued frequency of tuberculosis in children, and upon the relative frequency of intestinal and abdominal tuberculosis in children, must be accepted as conclusive evidence upon this point.

13. Even with children a consideration of the great frequency of bovine tuberculosis in certain regions, and of the absence of any record of tuberculosis affecting those supplied from a given "milk round" leads to the conclusion that the bovine bacilli have not heightened virulence.

14. The few positive records we possess of direct transmission of tubercle from cattle to man, through the agency of milk, indicate that infection is brought about only by the employment of milk of cattle which are very extensively diseased, more especially of those suffering from udder disease. Such milk contains enormous quantities of bacilli. In other words, large numbers of tubercle bacilli are required in order to infect human beings with bovine tuberculosis. This, again, is an indication that the bacillus cannot be regarded as having gained a heightened virulence for man, and that infection is not very readily communicated.

15. Animals showing physical signs of tuberculosis, and. above all, those exhibiting udder tuberculosis, should be condemned. and under no conditions should their milk be used for food.

16. When there is tuberculosis in a herd, Bang's method should be employed, the animals reacting to tuberculin being separated from the healthy ones. The milk from the reacting animals, for whatever

purpose used, should be so pasteurized as to effectively destroy the tubercle bacilli.

17. The great cause of infantile mortality is in-inflammation of stomach and intestines, and this is proved to be mainly brought about by the use of badly kept and fermenting milk. Wholly apart, therefore, from the question of tuberculosis, it is imperatively necessary that greater care should be exercised by all concerned in the distribution of milk. The general measures taken to lessen this, the greatest scourge of childhood—prohibition of the use of milk from cattle showing any form of sickness, pasteurization of milk, etc.—will equally lessen the danger of the transmission of tuberculosis from cattle to man.

The above conclusions adequately express the opinions of the majority of medical men who are opposed to Koch's dogmatic assertion that human and bovine tuberculosis are not intercommunicable. Dr. Adami is no partisan, but has approached the question with a perfectly open mind, and the deductions drawn by him as the result of investigations, observation, and a study of recent literature on the subject, are in a high degree reasonable.

The Medical Record, soon after the London Tuberculosis Congress had ended, took exception to Professor Koch's pronouncement on more than one ground. Attention was drawn to the fact on several occasions that even if Professor Koch were right as to the nontransmissibility of tuberculosis from cattle to man, he should have gravely warned farmers, milk-dealers, and the general public that precautions to guard against impure milk should be on this account in no wise relaxed, as diseases other than consumption may be disseminated by means of milk, not to mention the menace to child life by the contaminated article.

Dr. Adami takes practically the same view, and speaks of Professor Koch's carelessness in this respect as follows:

"It was his duty to have pointed out that his conclusions did not affect in the slightest the legislative and other measures adopted to reduce the dangers to cattle and to the agricultural community resulting from the spread of tuberculosis among cattle and domestic animals. Not doing this, he left it to be inferred that legislation against bovine tuberculosis is in excess of what is necessary. And this, it is right to protest, was little less than criminal on his part."

In Great Britain the pernicious effects of the German scientist's teaching have already been painfully evident, and it will probably take some years of education on opposite lines to dispel the belief that great care in procuring milk free from disease germs and in preserving it from after-contamination is unnecessary. It is to be hoped that those interested in the question in the United States will stand firm, and will use every endeavor to eradicate tuberculosis from cattle and to ensure a pure milk supply.

VOLTA BUREAU.

The second international report of schools for the deaf, made to and published by the Volta Bureau in Washington, D. C., contains a well-arranged compilation of pedagogic statistics from all the foreign and home institutions for the education of deaf-mutes. The provision and support of these schools by their respective governments exhibit a wide diversity of opinion as to the most approved method of instructing all grades, since it is impossible in public institutions to follow efficiently a system of individual instruction without incurring great expense in maintaining a large corps of thoroughly qualified teachers.

In Europe, as in this country, teachers seeking appointments in institutions for deaf-mutes are required to submit evidence of at least two years' training in actual daily work with these pupils, also to pass an examination in the science of speech and hearing. For advanced grades it is deemed requisite to possess a fair amount of knowledge of the relational anatomy of the larynx and ear. The report cites, in detail, the experience of each country employing the various systems, and while the concensus of opinion is very strongly in favor of the oral or lip-reading method, it would seem that the deaf-mute prefers a sign language.

By the oral method the students acquire actual vocal speech. Their attention is first drawn to the vibrations produced in the throat and chest of a speaker, and the correspondence of these to lip movements, until, very gradually, the pupil learns to produce sounds by the "feel," to recognize them on the lips by the sight, and to connect them with specific ideas and with written words. Thus this system removes many restrictions naturally placed upon the intellectual training and ordinary social intercourse of the deaf and dumb, whereas the sign language, though it affords the readiest means of deaf-mute intercommunication, limits the expression of thought. This naturally proves of great drawback, as the isolation of deaf and dumb brings about the deplorable tendency to intermarriage.

Difficult as the oral system is, demanding much individual attention, and, in consequence, necessitating an exceptionally large and expensive teaching staff, it is justified by those excellent results which transform a number of non-efficients into self-supporting members of a community. A combination of the two methods has proved aught but satisfactory, as the pupil, greatly to his own detriment in lip reading, invariably resorts to the easier sign language for conversation with his fellow mute.

The "simple pantomime" method, employed in teaching the so-called "Heathen Chinee," excites approval for the genius displayed by the instructors in overcoming those apparently unsurmountable philologic barriers in a language, whose only commendable feature is its monosyllabic construction. Again, the vocabulary of Indo-China is of such extreme complexity that lip reading is impossible, and dactylology is the only method suitable for the transference of ideas. In India, though the care of these deficients presumably devolves upon the government authorities, little or no attention has been given to their needs, and parents frequently desert their afflicted offspring as "possessed with a devil."

The report does not touch upon the subject of greatest interest to the medical profession, namely, treatment, although it states that many pupils pronounced incurables are found, after repeated experiments, to possess a very slight appreciation of sound waves, and that sensitiveness can be increased by constant training. Acting upon this belief, Germany tests all likely students by Dr. Bezold's continuous sound scale, and it is interesting to note that this country, recognizing the great progress made in the United States during the last decade, in improving the methods of deaf-mute instruction, has granted leave of absence to two of its head masters to study and report upon our systems.

Much difficulty is encountered in obtaining correct histories of pupils, and it is found that parents have great aversion to admitting the congenital nature of the child's defect, invariably attributing it to some infectious illness of infancy. It is a noteworthy fact that the English boards recognize tuberculosis as a potent factor in the causation of deaf-mutes, and a rigid observance of the laws of hygiene, with especial attention to physical culture, is now considered as part of the curriculum of the various institutions.

The universal cry from every institution has been for more money, and it would seem but just that a generous government education be bestowed upon this class of abnormals, who have, in no way, been party to their misfortune.

Dr. Lawrie on Cholera.

In connection with the wide-spread outbreak of cholera in the Philippines, the report of Lieutenant-Colonel Lawrie, I. M. S., upon the cholera epidemic in the Hyderabad dominions of India should be of interest. There are two points of interest, says Colonel Lawrie, regarding the purely medical aspects of the epidemic. The first is that we gave the plan of treatment by the intravenous inection of normal saline fluid a thorough trial in the first four cases which came under observation. The results, however, were disappointing, and all four patients died. To show the uncertainty and disappointment which attend active treatment in cholera it may be mentioned that the next five cases which occurred recovered without any special treatment beyond morphine injections to ease the cramps, and being allowed to drink unlimited amounts of liquids such as coffee.

The second point of interest regarding the epidemic relates to the nature of cholera. It is the universal rule to regard cholera as a bowel disease, and preventive inoculations have been practised with vaccines prepared from concomitant bacilli found in the intestinal tract. But it has long been known that the only signs of actual disease found on post-mortem examination are in the kidney, and the lesions found in the kidney, which vary from intense congestion to complete disorganization, are considered to be secondary to the bowel complaint. It is much more probable that these lesions are primary and constitute the disease.

In every case examined by himself and his assistants, Dr. Lawrie says, albumin was found in the urine from the earliest stage of the disease, as well as whenever it was possible to obtain any urine throughout its progress; and the recovery of the patient or his death, if he passed through the stage of collapse, coincided with the arrest or increase of the albumin passed from the kidney. The vomiting and purging which are so characteristic of cholera are not necessarily due to a lesion of the intestines, in which no disease is ever found sufficient to account for them, but are, on the other hand, perfectly compatible with rapid nephritis of a specific nature, with suppression of urine. The moment suppression of urine is threatened it is a matter of common knowledge that the system endeavors to get rid of the waste products which can no longer pass out by the kidney by some other channel, and the vomiting and purging which take place in cholera are fully accounted for by, and are illustrative of, this fact. They are, therefore, in all probability, not symptoms of disease of the bowel, but merely signs of an acute specific nephritis, which goes by the name of cholera.

The symptoms during life, therefore, point to disease of the kidneys, and they correspond with the only pathological signs found after death. If this view is correct and it is established that the disease is water-borne, there should be no insurmountable difficulty in tracing the virus to its proper habitat in the human body, and in eventually discovering an antidote for it.

The epidemic of cholera which is now devastating the Philippines should afford the United States military surgeons ample opportunities for studying the disease from all points of view, and especially from the bacteriological aspects.

The medical men of India are considerably handicapped in their efforts to trace the origin of cholera to its source, by the rigid caste rules which forbid post-mortem examinations among the native population. It would be worth the while of United States surgeons in the Philippines to endeavor to obtain accurate knowledge of the virus by searching bacteriological examinations of the kidneys of those who have died of the disease.

Colonel Lawrie may be wrong in his surmises as to the cause of cholera, but at the same time he is a man of acknowledged talent and he has had almost unrivaled experience in the diseases of the far East and of cholera in particular.

Drugs in the Treatment of Insomnia.

As to the value of drugs in the treatment of insomnia, diversity of opinion exists among the prominent specialists in nervous affections. Some there are who hold that the giving of narcotics is greatly abused, while others contend that the employment of such means for producing rest to mind and body, is justified in the majority of cases, or at any rate that the physician should be the best judge with regard to the use of narcotics.

At a recent meeting of the British Medico-Psychological Society, Dr. Henry Rayner read a paper on the subject which gave rise to an extremely interesting discussion. Dr. Rayner, himself (*Hospital* June 14) opposes strongly the custom of giving drugs for the purpose of producing sleep, and recorded his belief that a large amount of the nervous and mental disorders so prevalent amongst the well-to-do is due to the indiscriminate and injudicious use of soporific compounds.

Dr. G. F. Blandford takes an entirely different view and from an experience of forty years, stated that in cases of threatening insanity with insomnia as a marked feature, he felt as certain as he could feel of anything that a great number of these patients had been materially benefited by the use of medicines given to induce sleep. He further held that it was possible to give drugs in such doses as to produce a state which was indistinguishable from natural sleep, but it was necessary to select the drug suitable to the case. He thought that the profession as a rule were inclined to give too large doses of sedatives, and to continue the same for an unnecessarily long period. Paraldehyde he considered to be one of the best and safest narcotics.

Dr. Savage, while allowing that sleeplessness was the predominant symptom of the day in all nervous and mental affections, said that before treating it was necessary to first ascertain the cause. In anæmia of the brain, concerning which so much was heard nowadays, he was certain that a nightcap of grog with a little food were more likely to produce sleep than sedatives of the opium type. Again hydrotherapy in certain cases was of the utmost use with patients whose tissues were already loaded with toxic agents, who had taken too much alcohol, or were gouty. For persons in these conditions a dose of calomel followed by salines and baths was of great value in producing sleep as well as in curing the patient of his malady. Where much pain was present opiates and other narcotics assisted in inducing sleep, and this was especially so in cases of mental pain, and though it was true that opium upset the digestion, the rest which it produced was the means of the digestion being in turn improved. Referring to the more extreme use of narcotics Dr. Savage said that he had seen extremely mischievous patients narcotised into dementia, and on recovery from that condition get perfectly well. A morphomaniac could be given an ounce of bromide per day for several days and be found to have recovered at the end of that time.

Dr. Fletcher Beach said that in many cases of neurasthenia and brain fag little could be done unless sleep could be produced, and for this purpose he recommended the use of sulphonal, but he thought it was wrong to give narcotics continually for weeks. Dr. Percy Smith urged that patients who could not sleep at night should be allowed to sleep whenever they felt inclined to do so, and in regard to the drug treatment of insomnia said that he thought general practitioners had not yet fully realized that other drugs would produce sleep without the very bad effects of morphia.

The trend of the discussion seemed to veer in the direction of the use of narcotics, when employed intelligently and with discretion. Dr. Julius Mickle gave the key to the situation when he said that sleep producing drugs should be administered with brains.

Latterly, there has been somewhat of a hue and cry with respect to the prescribing of narcotizing mediums by the medical profession. The charge has been made more than once, that the physician has been in many instances responsible for the moral, mental and physical ruin of individuals through his zeal in recommending opiates for the relief of insomnia, of acute pain, and of various forms of nervous disorders. While this may be true to some extent, a careful scrutiny would probably show that the situation so far as the acts of the physician are concerned has been greatly exaggerated. Narcotics are sometimes absolutely indicated, indeed there is no other way known of successfully treating certain phases of mental and nervous affections. The first thing to do is to diagnose correctly and then if necessary to prescribe narcotics with due discrimination. Dr. Savage's remarks with respect to the efficacy of hydrotherapy and aperients in the treatment of alcoholics or of those whose systems were loaded with toxic agents were much to the point.

COMMERCIAL VALUE OF HUMAN LIFE.

It is now universally conceded that human life has a definite commercial value, and although different views are held in different parts of the world and in even various sections of the same country as to what is inferred by a definite value, all agree in allowing damages for injury or compensation to the surviving relatives of the person killed.

Mr. Marshall O. Leighton has a lucid article on the matter in *Popular Science Monthly*, June. Regarding the conditions governing judicial procedure in cases of this kind, the writer says, the principle generally adhered to in estimates of life values is well defined by the English Court procedure, and this has been followed in spirit if not in letter by the majority of the States of our union. It is, in effect, as follows: "The jury may give such damages as they shall deem a fair and just compensation with reference to the pecuniary injury resulting from such death."

Arrangement of the different cases of award for wrongful death, in the order corresponding to the age of the decedents, from the youngest to the oldest, shows a somewhat heterogenous mass of figures, often varying considerably in the same age column. This might be expected in such an arrangement, for mankind is widely diverse. The productiveness of an individual depends upon his habits, applicacation, thrift, mental acuteness, physical condition and many of the other personal qualities which accompany mankind. Where one individual may possess many of these, they may be partially or altogether wanting in another, and so the judgment of juries and courts is altered to meet these conditions in the individual.

Dividing the life into age periods of five years, and combining the awards in each period, it is found that the resulting average in each period is thoroughly representative of the whole group and possesses tolerably narrow limits of probable error.

Mr. Leighton then gives a diagram in which it is shown that in varying degree the value of life increases up to the age of thirty which is the culminating point of physical vigor. At that age the physical powers are supposed to wane and therefore the risk becomes greater and the confidence in future values is lowered,

After the age of thirty; there follows a gradual decline of values until the age period, fifty-five to sixty, is reached, when the declivity becomes sharp, remaining so to the end.

Conclusions arrived at are as follows:

1, The pecuniary value of life is subject to the same economic laws as are applied to the more vulgar commodities.

2. In courts of law, the measure of an individual's productiveness, which is the measure of his value, receives the most careful scrutiny; therefore the decisions of such courts, where existing statutes permit, are trustworthy in determining an individual's value to his family.

3. The pecuniary value of a life to its relatives represents its pecuniary value to society.

4. Damages given for wrongful death are such that they can be represented by an average in diferent age groups, with only narrow limits of probable error.

5. The relation of these age-group values, one to the other, is supported by common observation and statistical reasoning.

Two Cases of the Removal of the Gall-Bladder by Finney's Method.—Ingersoll Olmstead reports two successful cases of this operation. It consists in leaving a flap on either side of the liver attachment of the gall-bladder, composed of the seromuscular coats, sufficient when the two are approximated to cover up completely the abraded area. The stump, on the other hand, is treated like an appendix stump, thus preventing any ordinary possibility of a leak from this source. When the gall-bladder is diseased it is best to get rid of the whole organ without opening its cavity, thus precluding the possibility of infection from that source.—*The Canadian Practitioner.*

News of the Week.

The Public Health and Marine Hospital Service.—One of the last acts of the House of Representatives was the passage of the bill making the Marine Hospital Service the Public Health and Marine Hospital Service. The object of the bill, it was explained during the closing debate, was to enable the Federal Government to take charge of the quarantine service of the country, in compliance with a growing public demand. Heretofore it had been rendered impossible of achievement because of the lack of coöperation between the health officers of the States and of the nation. The passage of the bill was opposed by several members, who contended that it would secure no practical advantage to the country, while the gathering of statistics provided for in the bill would be better done by the new permanent census bureau. The antagonism was not very spirited, however, and the House finally voted to suspend the rules and pass the bill.

The "Dixie" to Be a Hospital Ship.—The cruiser *Dixie* is expected to arrive at the Brooklyn Navy Yard in a few days from the League Island Navy Yard at Philadelphia to be transformed into a hospital ship. The work will cost about $75,000, and will be in charge of Naval Constructor Capps.

A Large Bequest to St. Thomas's Hospital, London.—Mr. Charles Gassiot, who died in London in May leaving an estate of over £830,000, left £26,000 to various charitable institutions, and £250,000 to St. Thomas's Hospital.

Dr. Deaver's Appendicitis Statistics.—Dr. John B. Deaver of Philadelphia calls attention to an error in the report of his paper upon appendicitis read at Saratoga. It was stated in the report that 137 chronic cases were operated with 7 per cent. mortality; but the mortality in the chronic cases was in fact only $\frac{7}{10}$ per cent.

The International Sanitary Conference.—The following delegates have been appointed by the Secretary of the Treasury to attend the international sanitary conference to be held in Washington, D. C., in October next: Surgeon-General Wyman, U. S. Marine Hospital Service; Passed Assistant-Surgeon M. J. Rosenau, U. S. Marine Hospital Service; Dr. H. L. E. Johnson, Washington, D. C.; Dr. Arthur K. Reynolds, Commissioner of Health, Chicago, Ills.; Dr. Edmond Souchon, President of the Louisiana State Board of Health, New Orleans, La.; Dr. J. Y. Porter, State Health Officer of Florida, Jacksonville, Fla.; Dr. A. H. Doty, Quarantine Officer, Port of New York; Dr. L. M. Powers, Health Officer, Los Angeles, Cal.; Dr. Charles B. Adams, Iowa State Board of Health, Sac City, Ia.; Dr. F. W. Porterfield, Atlantic, Ia.; Dr. Fred W. Powers, Iowa State Board of Health, Reinbeck, Ia.; Dr. James T. Priestly, Surgeon-General, Iowa National Guard, Des Moines, Ia.

International Conference of the Societies of the Red Cross.—Of the many propositions and resolutions submitted to this conference, held in St. Petersburg, May 29–June 4, the following are the only ones which were adopted:

Submitted by Germany: (*a*) In order to prevent the abuse of the distinctive sign of the Convention of Geneva as concerns international assistance, the personnel sent by the Society of a neutral State and admitted for this purpose, will bear the armlet of the Geneva Convention with the stamp of the National Committee which is authorized to send it. (*b*) The armlet carries beside the stamp of identity, affixed by the competent authorities of the belligerent Power to the sanitary assistance of which the personnel has been sent. Furthermore all the baggage destined to this assistance are to be made recognizable exteriorly by the application of the said stamp of the National Committee of the neutral State. (*c*) Each member of the Sanitary Mission sent by a neutral State will receive a card of identity to be delivered by the competent authorities of the belligerent State, in the language of the latter. (*d*) All missions not identified as above stated and which pretend to devote themselves to administering to the wounded and sick, shall not be admitted by the belligerent Powers. (*e*) The societies bind themselves to apply to their respective governments for the permission hereby required.

The following was introduced by the Central International Committee of Geneva: (*a*) It is the right and duty of each State to exercise a strict watch over private expeditions of assistance organized on its territory. National societies of the Red Cross are bound to assist in this investigation. (*b*) No expeditions of any kind are to leave the territory of a State without having in advance obtained the permission of the government. (*c*) No expedition of assistance has the right to make use of the name of the Red Cross, even should it have received the authority of the Government, unless it should have been organized or recognized by a society empowered to use that name.

The following resolutions, introduced by the Central Committee of Russia, also received the approval of the Conference: (*a*) It is desirable that societies of the Red Cross should come to an understanding with maritime companies, in order that the latter should place vessels of great speed at their disposal for the sanitary service in time of naval wars. The cost of hiring and adapting these vessels to be borne by the Red Cross societies. (*b*) That the best system of adaptation and equipment of hospital ships should be studied by all the societies of the Red Cross. (*c*) That in order to insure to the Red Cross societies the proper life-saving material and experienced hands, an understanding should be arrived at between the Red Cross and Life-Saving societies.

To prevent the abuse of the emblem of the Red Cross Societies: (*a*) It is to be desired that each government instructs the proper officials not to grant patents or trade marks bearing the insignia and name of the Red Cross. (*b*) That a period (for example, one year) be accorded for the purpose of enabling such industrial and commercial bodies as had adopted the insignia of the Red Cross to retire the same. (*c*) After the delay named, all infringements of this law may be punished by imprisonment or fine, as the case may be, at the instance of the Government or that of the societies of the Red Cross.

The conference recommended that the signatory Powers of the Geneva Convention regulate the legal basis upon which international assistance, given by the neutral societies of the Red Cross to belligerent States, might be placed in the theatre of war. It also urged that the signatory Powers of the Convention of the Hague, July 10, 1899, take measures to re-embody article 10 excluded by that Convention. In this case the societies of the Red Cross would bind themselves to treat the sick and wounded, without regard to nationality, brought to ports and maritime towns by naval vessels. Article 10, above mentioned, is as follows: "Sick, wounded, or shipwrecked persons who are sent to a neutral port, with the consent of the local authority, shall, unless a contrary arrangement be entered into between the neutral State and the belligerents, be subjected to such restraint by the neutral State that it will be impossible for them to again take part in the operations of the war. The expenses of hospital treatment and interment of the sick, wounded, and shipwrecked shall be borne by the State to which they belong."

Appointments and Resignations.—Dr. H. V. Wurdeman has been elected Professor of Ophthalmology in the Chicago Eye, Ear, Nose and Throat College.

Dr. Wm. M. Angney has been appointed Chief Surgeon to the Department of Public Safety of Philadelphia in succession to Dr. Thos. H. Andrews, resigned.

Dr. P. F. Moylan has been appointed a member of the visiting medical staff of St. Joseph's Hospital, Philadelphia.

Dr. Thos. H. Andrews has resigned as chief surgeon of the Philadelphia Bureau of Police and Fire, a position he had occupied for fourteen years.

Dr. J. Edward Stubbert, who has been physician in charge of the Loomis Sanitarium since its opening in 1896, has tendered his resignation, but will continue as a member of the medical board.

Dr. John H. Girdner of this city has declined a reappointment as trustee of the New York State Hospital for Tuberculosis, and Governor Odell has appointed Mr. John Seeley Ward to fill the vacancy.

Louisiana State Medical Society.—At the annual meeting of this society, held at Shreveport, June 3-5, the following officers were elected: *President*, Dr. Isadore Dyer of New Orleans; *Vice-Presidents*, Drs. H. B. Gessner of New Orleans, E. D. Martin of New Orleans, W. E. Barker of Plaquemine, F. M. Thornhill of Arcadia, J. C. Willis of Homer, and Charles McVea of Baton Rouge; *Recording Secretary*, Dr. W. M. Perkins of New Orleans; *Corresponding Secretary*, Dr. A. G. Friedrichs of New Orleans; *Treasurer*, Dr. H. S. Cocram of New Orleans.

The American Proctologic Society.—The fourth annual meeting of this society was held at Saratoga Springs on Tuesday, June 10, 1902, under the presidency of Dr. Thomas Charles Martin of Cleveland, Ohio. The following officers were elected to serve during the ensuing year: *President*, Dr. Samuel T. Earle, Baltimore, Md.; *Vice-President*, Dr. Floyd W. McRae, Atlanta, Ga.; *Secretary and Treasurer*, Dr. William M. Beach, Pittsburg; *Executive Council*, Drs. George J. Cook, Indianapolis; Lewis H. Adler, Philadelphia, Thomas Charles Martin, Cleveland.

The British Anti-Vivisectionists have got a little bill into the House of Commons seeking to abolish anæsthetics except those given by inhalation, to forbid experiments for the purpose of demonstration, to require license for each single experiment, to insist on the presence of one inspector throughout every experiment, and other impracticable provisions.

The Late Dr. Edwin W. Pyle.—At a meeting of the New York Otological Society, held March 24, 1902, the following was adopted: *Resolved*, That the members of the New York Otological Society receive with profound regret the announcement of the death of our esteemed colleague, Dr. Edwin W. Pyle. *Resolved*, That in the death of Dr. Pyle this society looses an earnest and conscientious member and otology an enthusiastic and scholarly disciple. *It is hereby offered*, That this expression of the society's regard be spread upon the minutes of the meeting in the form of resolution, and that an engrossed copy of the same be presented to the family of Dr Pyle.

Committee for the Society, Fred Whiting, M.D.

A Reception to Dr. Presley M. Rixey, Surgeon-General, United States Navy, was tendered on June 14, by the Medical Club of Philadelphia.

The Hospital Graduates Club.—The annual dinner of this society took place on May 26 at the Manhattan Hotel, Dr. W. E. Lambert, presiding. Addresses were made by the Rev. Dr. Greer of St. Bartholomew's Church; Prof. O. Haab of Zurich, and Drs. Wm. M. Polk, James E. Newcomb, D. Bryson Delavan, and George T. Harrison of New York city.

The North Carolina Medical Society.—At the forty-ninth annual meeting of the Medical Society of the State of North Carolina, held at Wilmington, under the presidency of Dr. Robert S. Young of Concord, the following officers were elected: *President*, Dr. A. W. Knox of Raleigh; *Secretary*, Dr. J. Howell Way of Waynesville; *Treasurer*, Dr. G. T. Sikes of Grisson. The next annual meeting will be held at Hot Springs.

The Late Dr. Oren D. Pomeroy.—At a meeting of the New York Otological Society, held May 27, 1902, the following minutes and resolutions were adopted: *Whereas*, Death has removed from among us a former member and one of the founders of this society, Dr. Oren D. Pomeroy, long and favorably known and respected among us, *therefore be it Resolved*, That we deeply regret the loss we have sustained in the demise of one of the pioneers of otology in America, and one who, until illness clouded his advancing years, kept fully abreast with its advances. *Resolved*, That we extend our sympathy to the bereaved family of the deceased and that a copy of these resolutions be spread in full upon the minutes of the society.

Committee, N. G. Hepburn, M.D.
J. B. Clemens, M.D.

Obituary Notes.—Dr. James T. Jelks of Hot Springs, Ark., died suddenly on June 24, at the age of fifty-three years. He was a graduate of the Medical Department of the University of Nashville in 1870. He was professor of gynecology and syphilology at the Barnes Medical College, St. Louis, and was formerly professor of genitourinary surgery and venereal diseases at the College of Physicians and Surgeons, Chicago. He was editor of the *Hot Springs Medical Journal*.

Dr. Robert A. Work died at Bethlehem, Pa., on June 17, at the age of thirty-four years, following an operation for appendicitis.

Dr. Alexander M. Mecray died at Maple Shade, N. J., on June 26, as a result of an apoplectic seizure, at the age of sixty-three years. He was graduated from the medical department of the University of Pennsylvania in 1863. He was at one time president of the Camden Company Medical Society and for many years a member of the staff of Cooper Hospital.

Dr. Arthur Ward died at his home in Newark, N. J., on July 6. He was born in Belleville in 1823, his father being a well-known physician, Dr. Samuel L. Ward,. He was graduated from Yale College in 1844 and then studied medicine at the College of Physicians and Surgeons in this city, his preceptor being Dr. Thomas Cook. He obtained his medical degree in 1847, and had practised in Newark continuously since that time. Dr. Ward enjoyed a very extensive practice and was beloved by colleagues and patients for his kindly disposition and abundant charities.

Dr. Charles C. Furley died at his home in Wichita, Kan., on July 6, of tuberculosis. He was a graduate of the Cooper Medical College, San Francisco, in 1860, and served throughout the Civil War as surgeon in the Union Army. At the close of the war he settled in Wichita, and at the time of his death was the oldest medical resident of that city.

Correspondence.

VACATION COURSES FOR POST-GRADUATE STUDY IN BERLIN.

To the Editor of the Medical Record:

Sir: Especially available to those desiring to pursue brief post-graduate study in Berlin are the Ferien-Curse that are given twice yearly, preceding and following the regular winter term of the university.

These are exclusively for graduates in medicine, usually practitioners of some experience, are of a month's duration given by a Docenten-verein that numbers some 125 members, for the greater part professors and privatdocenten of the university.

No less than 175 courses are offered, arranged with the usual precision and detail, so that one may pursue, without conflict in hours, studies in various subjects. There are but few didactic lectures, and the classes are usually limited to a maximum of from three to ten members. The fee ranges from 20 to 150 marks.

In pathology courses are offered by Langerhans; in internal medicine by Furbringer, Frankel, Renvers, Ewald; in children's diseases, by Professor A. Baginsky, at the Kaiser and Kaiserin Friedrich Hospital. A rapid review of recent therapy is given by Klemperer, and Grunmach demonstrates the Röntgen rays in physical diagnosis. Professor Posner, who had charge of the great jubilee in celebration of Virchow's eightieth birthday, gives a course in cystoscopy.

In surgery there are courses by Professor Gluck and F. Krause, and Drs. Lexer and Borchardt. The early morning course upon the cadaver, formerly given by von Bergmann, is now conducted for the Ferien-Curse by Borchardt. In gynecology there are Dührssen, Landau, Ruge, Koblanck; and all the operations may be practised upon the cadaver under Strassmann and others. Orthmann, though not a member of the Verein, usually forms a class at this time.

One may be one of three to spend twelve hours a week with Professor B. Baginsky in the treatment of ear diseases, or a similar period in treatment of throat and nose, or may be given excellent opportunity for operative work upon throat and nose in the clinic of Professor H. Krause, or with Jansen see many ear, nose, and throat cases, and witness some radical surgery. Bernhardt, Oppenheim, and Remak give clinics in nervous diseases.

The course given through the month of October is, perhaps, the most popular. Toward the latter part of the month von Bergmann and Oleshausen begin again to operate with an abundance of selected material, and throughout the month the operating rooms of Israel, Güsserow, and Koenig may be visited, as also the great pathological collection of Virchow. At the new institute for the study of infectious diseases Robert Koch is accessible, and courteous even to the casual visitor, and, under generous State endowment, is arranging to give systematic instruction.

Your recent review of post-graduate instruction is most desirable, but hardly complete without mention of the Ferien-Curse of Berlin.

Daniel B. Hardenbergh, M.D.

Middletown, N. Y.

REMOVAL OF THE APPENDIX.

To the Editor of the Medical Record:

Sir: Some six or seven years ago I adopted a new method of removing the vermiform appendix. Up to that time it was the custom with all the operators I had seen performing this operation to tie the appendix about a quarter or half an inch from the cæcum with silk or catgut, and then to cut it off a quarter of an inch above the ligature, this leaving at least half an inch of the diseased organ. Some, but not all, took the precaution to cut only through the peritoneal coat half an inch above the cæcum, the peritoneum being then peeled back until the root of the appendix was reached when it was tied and cut off. As a rule, a drop of pure carbolic acid was dropped on the gaping diseased mucous membrane so as to disinfect it, or it was touched with the actual cautery. These two expedients are very good as far as they go, but they have no effect upon the mucous membrane closely brought in contact by the ligatures, and as mucous surfaces never unite they go on secreting again just as soon as the ligature has sloughed off. The result is a fecal fistula, which keeps the patient in hospital three or four months and generally requires a prolonged and exceedingly difficult operation for its cure.

Having seen and heard of this accident in a considerable number of cases, I introduced a method by which it is entirely avoided; and brought it to the attention of the Surgical Section of the British Medical Association when it met in Montreal several years ago. It consisted simply in cutting the entire appendix off flush with the cæcum and then treating the circular opening in the bowel precisely as I would a bullet wound with Lembert sutures, first securely fastening the muscular walls together and then covering them over with one or two layers of sutures of the peritoneum. With this method I have not had a single fecal fistula in my practice. Within the last year I have made another improvement by which the same result is obtained with a much less expenditure of time. My assistant draws the appendix tightly upward and I then pass a purse-string suture around the base of it on the peritoneum and muscularis of the cæcum and the appendix is cut off even with the bowel and at the same moment the purse-string suture is tied firmly, by which means the *cut edges* of the mucous membrane are brought in contact and unite, and the peritoneum unites over it, making a water-tight seal in a few minutes.

While on this subject I would like to say a few words of condemnation of the method of leaving the diseased appendix intact and merely turning it outside into the bowel. In some of the cases I have had, the opening of the appendix into the cæcum was so contracted that it could not have been invaginated, while even if it could I maintain that it is bad surgery to leave an infected organ which it is so easy to remove completely by the above method and which is no longer required by the economy.

A. Lapthorn Smith, M.D.

Montreal, June 23.

MOSQUITOS AND MALARIA.

To the Editor of the Medical Record:

Sir: In Henry M. Stanley's note-book, under date of Oct. 5, 1888, appears the following note, which, in view of recent discoveries, is interesting: "Emin Pasha informed me that he always took a mosquito curtain with him, as it was an excellent protector against the miasmatic exhalations of the night." Question, might not a respirator attached to a veil or face screen of muslin assist in mitigating malarial effects? In Darkest Africa, p. 33, vol II. So near did this scientific Pasha come to discovering the connection between mosquitos and malaria.

Frederick A. Wright.

New Milford, Conn.

The Treatment of Fractures.—N. Wolkowitsch believes that the protracted disuse of the entire limb that accompanies the usual immobilization treatment of fractures militates greatly against the rapidity of the cure. In consequence of the enforced inactivity the muscles atrophy exudates are but slowly absorbed and the circulation is sluggish, so that bony repair is retarded. In some forms of fracture, such as those of the upper extremity of the humerus, he uses no retentive dressing whatever, simply allowing the wrist to rest in a sling. From the very first, daily massage and passive motion are begun, beginning very gently, later more actively, as the pain and swelling subside. For a routine dressing for most fractures molded plaster of Paris splints are recommended. These are prepared by wrapping longitudinal and circular turns of ordinary wet plaster bandages on strips of cardboard three inches wide and of the requisite length, until a sufficient thickness has been reached. The splint is immediately applied to the limb, which has been previously smoothly covered with a flannel bandage and is molded to shape, after which a second flannel roller is applied over all. In fractures of the lower extremity, the patient is allowed to walk as soon as the plaster has set; a cane, but no crutches, being given him. In compound fractures the condition of the wound determines the time of the beginning of the ambulatory treatment. The usual form of splint used is a "stirrup splint" consisting of a single strip prepared as described and passing down the legs on its outer side, under the arch of the foot and up again on the inside, thus permitting fairly free motion at the ankle in walking. In fractures of the leg the splint ends below the knee, in those of the thigh it is carried higher. After resections, such as those of the knee, a spiral turn, giving posterior support, is added. The results by this method, which has been used by the author for over seven years, show a decided shortening of the time necessary for firm union and a general improvement in functional results.—*Deutsche Zeitschrift fur Chirurgie.*

Progress of Medical Science.

The Boston Medical and Surgical Journal, July 3, 1902.

On the Classification of the Benign Thyroid Tumors.—Joseph Hersey Pratt divides the benign glandular thyroid tumors into three primary classes: (1) Simple adenoma, (2) fetal adenoma, (3) papilliferous adenoma. The first is the most common form and includes endemic goiter. It seems evident that the other forms of goiter described by Virchow—fibrous, colloid, and cystic—belong to this same primary type. Simple adenoma may be multiple, but is usually single. It may be diffuse or encapsulated. Its histological appearance lends support to Wölfler's theory that simple adenoma is formed by the growth of scattered groups of embryonic thyroid cells, which are found in the intervesicular tissue. Fetal adenoma are composed of solid masses of rosettes of epithelial cells, with little or no colloid, and the structure resembles the fetal thyroid. Papilliferous adenoma has branching papillæ lying in cystic spaces, (*a*) developing from the walls of old cysts, (*b*) true adenocystoma resembling the adenocystoma of the ovary.

Tuberculosis of the Prostate.—L. R. G. Crandon says that the diagnosis of tuberculosis in the prostate, since the disease may be primary here, is of great importance. A gleet or a catarrhal prostatitis persists; there is pain in the prostate or neck of the bladder, there may be a drop of blood at the beginning of micturition instead of at the end, as in stone. There is increased frequency of micturition, and perhaps burning. The urine is slightly turbid, but in it are no renal elements as in pyelonephritis. The prostate, examined by rectum or bimanually, is found to be soft, slightly enlarged and tender, especially far back and including the area of the trigonum. One or both vesicles may show enlargement, but this is probably secondary. To rule out stone finally the sound should be used, but with the greatest gentleness. Malignant disease must be borne in mind. Tuberculosis elsewhere in the body, old or recent, helps in the decision, and the bacilli may sometimes be found in the prostatic milkings, or the secretion may cause tuberculosis when injected into a guinea-pig.

Tuberculosis of the Testicle.—Paul Thorndike and W. T. Bailey have collected seventy-five cases. In only 20 per cent. of the cases were there any symptoms referable to the urinary tract, and in only 16 per cent. was the vas deferens palpably involved at the time of operation. The first statement means that in most of the cases operations, if done at all, were preformed either because of the mere presence of a diseased focus, or in order to palliate or remove an active inflammatory mass. The presence of small masses is insufficient as an operative indication, and the bulk of the cases are not operated upon until more acute local symptoms render such a procedure necessary. This means that most cases do not come to operation until a fairly late stage in the development of the disease. In the cases collected the testis as well as the epididymis was involved thirty-two times out of seventy-five. As to the second point, the frequent non-involvment of the vas deferens, the important question suggested is: Is it necessary to remove all the diseased area in order to benefit the patient? The author holds that partial removals are often of the greatest benefit, and says that it must be true that the removal of a large focus of disease in this region is often of the greatest value, just as is a similar removal in cases of typical or atypical resection of an involved joint, where one does not necessarily remove all of the disease in order to accomplish a great benefit to his patient.

Journal of the American Medical Association, July 5, 1902.

Nephrectomy, Subsequent Nephrotomy, and Finally Suprapubic Cystotomy.—A case presenting the stages indicated in the title is reported by E. D. Ferguson, his patient being a boy of eight years. Radiography showed calculi in both kidneys. Successive attacks of renal colic led to the necessity of the operations detailed. The result was favorable, the patient having stood all the operative measures well.

The Treatment of Pneumonia.—N. S. Davis, Jr., discusses the use of blood-letting, tartar emetic, blisters, poultices, veratrum, calomel, etc., all from the historical standpoint. To-day he notes the establishment of what may be called the eliminative plan. The sources of danger in pneumonia are: (1) The toxins produced by the diplococcus lanceolatus; (2) The rapid involvement of large areas of lung tissue in inflammation which makes them functionally useless; (3) The sudden distension of the right ventricle to the point of paralysis by obstruction of the pulmonary vessels; (4) Œdema of the lungs, the result of a weak heart, enfeebled respiration, and probably of toxins which excite œdema in tissues no longer possessing the vitality required to develop the changes characteristic of inflammation. Acting on this theory, we should look carefully after the bowels, use milk, broths, gruels, etc., for food, give water very freely, relieve cyanosis by oxygen, care for the heart (digitalis being the remedy par excellence); give strychnine as a respiratory tonic, employ the diffusible stimulants, such as the ammonia salts, and for antipyresis rely on cold packs and ice-baths. Opium should be used with the greatest caution, if at all. Davis does not believe in the utility of antitoccic serums in this disease. Destruction of the sputa should be effected as in tuberculosis or diphtheria. An antiseptic mouth wash should be used several times daily. The most careful observation of sick-room hygiene must be insisted on.

Medical News, July 5, 1902.

A Plea for the Simpler Medicinal Treatment of Chronic Nervous Diseases.—Joseph Collins warns against the abuse of drugs. In regard to the treatment of tabes, he believes in telling the patient that he is afflicted with a disorder that will eventually incapacitate him, but that in the mean time a number of years of activity remain to him, and by pursuing an appropriate line of treatment, and by the observance of the rules of hygiene, this period may be greatly extended. Non-medicinal measures, such as massage, suspension, electricity, hydrotherapy, dieting, and conformation to the best hygienic measures are very powerful therapeutic agencies, and the best in our power to stay the course of the disease. The best treatment of epilepsy is to put the system in such a condition that excitants of epileptic attacks, such as autointoxications from the gastrointestinal tract, from fatigue, from poisonous products, which should be eliminated from the body, will not develop within the body, and also to guard against those experiences which we have learned often precipitate attacks. Also to so influence neuromotor irritability in a sedative way that discharge of energy in the shape of explosion will be less likely to occur. As to neurasthenia, the writer finds that its treatment by rest, exercise, change of environment, isolation, hydriatics, massage, diet, avoidance of deleterious indulgences, and conformation to hygienic rules is so far superior to drug-therapy that he rarely uses drugs in these cases, unless to fulfill some pointed indication. It is not that the writer does not believe in the right use of medicine, but he calls attention to its frequent abuse.

Tetany.—Sanger Brown carefully discusses this subject. Pregnancy and lactation furnish a large proportion of the cases met with in women. Thyroid deprivation, due either to surgical interference or to disease, may cause tetany. Certain gastrointestinal disorders, such as diarrhœa and constipation, sometimes have an etiological significance. The acute infections are answerable for some cases. Hysteria is frequently, and epilepsy is sometimes, associated with tetany. This affection is most common in young adults. No post-mortem findings have as yet thrown any light upon the nature of the disease. Muscular spasm is the essential feature of tetany. As a rule, the spasm lessens during sleep. The electrical excitability of both nerves and muscles is greatly increased. The distribution of the spasm is, perhaps, more variable than its nature. The spasms are nearly always symmetrical. There may be certain sensory phenomena, such as tingling and burning. Vasomotor and trophic phenomena, as œdema of the parts of the seat of spasm are common. Some cloudiness of the lens is said to be present in some cases. In typical cases the diagnosis is not difficult. There is a wide variability in the duration of the disease, from a few hours to months. In cases resulting from extirpation or atrophy of the thyroid the treatment is obvious. Excepting for thyroid and pregnancy cases, no specific has yet been discovered. The relief afforded by sedatives and antispasmodics is often urgently demanded. The degree of medication of any kind necessary to subdue severe paroxysms demands the presence of a physician. In conclusion, it may be stated that the disease is characterized by tonic spasms, paroxysmal or continuous, and usually symmetrical, limited to the hands and feet in mild cases, but much more extensive in severe ones. Sensory and general symptoms, when present, are almost invariably distinctly subordinate.

New York Medical Journal, July 5, 1902.

The Eye as a Factor in Causing General Symptoms; Illustrated by the Report of a Case.—J. L. Minor relates the case of a negro woman of sixty-seven years who was troubled with severe pain in the right eye, spreading over the face and forehead and finally involving the entire body. The physician in attendance pronounced the case to be one of bilious fever and prescribed the usual remedies. Minor found the condition to be one of absolute glaucoma with loss of vision, requiring no immediate treatment. In the meantime. after a remission of symptoms, the pains had again returned, this time starting from the left eye. The latter showed acute glaucoma, demanding a prompt iridectomy. This was done and the general symptoms were entirely relieved.

The Differential Diagnosis of Acute Polyarticular Rheumatism, from a Surgical Standpoint.—Dr. W. G. Stern calls attention to present views on the infectious nature of rheumatism, but notes that it is at times difficult to differentiate between this disease and other infections having the seat of their activity about joints. Bacteriology does not always help us out for as yet there is no known definite germ of the former malady. The features of acute polyarticular rheumatism which may, however, lead to difficulty in diagnosis are (1) The disease may exceptionally manifest itself in only one joint throughout its entire course; (2) It may be of such a mild type and the effusions so scant as to be difficult of demonstration, and yet present later on all the grave endocardial symptoms of a severe case; (3) The initial acute symptoms and the polyarticular character may be masked, and the disease end with a sudden attack upon some one joint, which becomes tensely swollen, especially painful, the periarticular tissues infiltrated, and the joint itself securely ankylosed; (4) The swelling may not always be situated within the joint capsule. At times the neighboring tendon sheaths or the subcutaneous tissues become involved, making the impression of a phlegmon or lymphangeitis. This, however, only comes on late in the course of an attack. The diseases which can simulate acute polyarticular rheumatism, and from which a differential diagnosis must often be made, are briefly classified under two general heads: (1) Primary forms of arthritis, such as acute pseudo-rheumatic tuberculous arthritis, synovitis serosa, synovitis purulenta and arthritis purulenta, intermittent hydrops, syphilitic arthritis and arthritis deformans: (2) arthritis secondary to infectious diseases, septic infection, septicæmia or constitutional diseases. These are gonorrhœal arthritis, arthritis after scarlatina, pneumonia, diphtheria, etc., arthritis in septicopyemia, acute osteomylitis, osteochondritis (syphilitic and rachitic), arthritis in pulmonary tuberculosis, gout and joint neuralgia or neuroses. The paper follows out the lines above indicated.

American Medicine, July 5, 1902.

Ovarian Irritation as a Factor in the Etiology of Pseudocyesis.—J. Thompson Schell, in the cases which he reports, calls attention to the fact that all of the women were comparatively young, their ages being respectively 33, 29, 33, and 28 years, therefore they could hardly be classed as being at the menopause. The mental attitude of these patients was indifference as to the probability of pregnancy. Since their minds had been freed of delusional pregnancy, they had all been annoyed by more or less severe symptoms of ovarian disease. The writer thinks that pseudocyesis is probably a manifestation of hysteria, but he suggests that a pelvic irritation is the possible cause of the hysteria in some cases. He firmly believes that there are some cases, and possibly a larger number than we now have any idea of, in which the hysterical condition is brought about by some form of ovarian disease.

Six Cases of Epilepsy Due to Ametropic Eye-Strain.—George M. Gould, commenting on the reported cases, says that it has been asserted that epilepsy has been caused by imbalance of the ocular muscles and cured by operation, but this cannot be true if, according to the writer's belief, the incoördination of the external ocular muscles is itself the result of ametropia. Ametropia does occasionally cause epilepsy. It may be said that in the experience of others, eye-strain is not a casual agency in the production of epilepsy, but to this it may be replied that (1) Undoubtedly eye-strain is not the most common, and perhaps it is a relatively uncommon cause of the disease; (2) Nevertheless, however seldom it may be the cause, it should not be neglected, on account of the terrible mystery and incurability of the dread affection; (3) The relief of eye-strain is far from certain with the prescription of glasses, even by the most reputable of oculists, because there are a hundred ways in which the prescription may not be correct, the glasses may be improperly worn, or the ametropia may change rapidly.

Philadelphia Medical Journal, June 5, 1902.

Climatology of California.—Alexander G. McAdie sums up the general climatic factors of this land of sunshine and fog, of heavy rainfall and of scant rainfall, this land of contrast—California: Because of its proximity to the ocean, a great natural conservator of heat the temperatures are as a rule moderate and equable. Because of the exceedingly diversified topography the climatic conditions are likewise very diversified, the prevailing easterly drift of the air brings a constant supply of fresh air neither too hot nor too cold to most of the State; and, owing to the general path of storm movements lying further to the north, California escapes many of the disturbances so familiar elsewhere. All these combine to give a climate different from other sections of our great country. The effect of the climatic environment is well shown in the flora of the State. What influence the climate will exert on man, and what the ultimate record will be, the writer does not discuss.

Carcinoma of the Eyelids, with Secondary Involvement of the Eyeball: Removal of the Growth by Extensive Plastic Operations; Recurrence.—William Campbell Posey and Edward A. Shumway report this case. The patient was a woman sixty-one years of age. The right eyelid was ulcerated to such an extent that it was threatening the loss of the eye. The ulceration had originated in a small mole at about the middle of the lower lid some ten years before. The ulcer was painless. Her health was excellent. The left eye had been removed on account of glaucoma. Extirpation of the growth was advised although the loss of the eye was probable. The ulcerated areas were excised, which left large denuded areas. The growth had extended deep into the orbit and severe hemorrhage occurred on its removal. In order to fill in these denuded areas, several flaps were taken, one from the cheek, one from the temple, and one from above the root of the nose. Three days later the stitches were removed and the globe was found to be in excellent condition. Sight was as good as before the operation. Three days later, however, signs of panophthalmitis developed. At the end of three weeks, after the greatest care, the eye was almost quiet. Two years after this the patient returned to the hospital for the relief of intense pain in the eye and temple which had annoyed her for several months. The globe was in a state of absolute glaucoma and the orbit seemed to be completely filled up with an epitheliomatous mass. The whole region was cleaned out, and recovery was rapid. The last time the patient was seen, six months after the operation, there had been no recurrence.

The Lancet, June 28, 1902.

Brief Notes on Three Cases of Auto-Intoxication; One Fatal.—A. B. Duprey calls attention to a common condition in Grenada where corn and peas form the main articles of diet. Constipation is very common, owing to the diet which also includes many fruits of a fibrous texture. As a result of the bowel inactivity a train of symptoms is set up, strongly suggestive of uræmia and caused by absorption from the intestine. Soap and water enemas with castor oil generally relieve the condition. Three cases are reported in detail. One is that of a child who died suddenly but the history of the case and results of autopsy led the author to include it in the present category.

On the Treatment of Incipient Bronchopneumonia in Infants.—The paper of T. Zangger is a plea for hydrotherapy. His plan of treatment is as follows: At the very first onset of pneumonic symptoms (high temperature, diminished resonance, small noncrepitant or crepitant râles, apathy, increased rate of heart beat and respiration) he gives a bath of 86° F. for two minutes and then slowly reduces the temperature of the bath by adding cold water for from two to three minutes till a temperature of 76° is reached. He rubs the body of the patient with a sponge or cloth or the hand to promote reaction of the skin and reduction of the body heat. The bath water need not, and in cases of feeble children, should not, quite cover the body but the water can be sponged on the chest, the patient lying in the arms of an attendant. If definite pneumonic symptoms be present the bath may have to be repeated at intervals of from eight to twenty-four hours. The cross packs relieve the symptoms of bronchitis. Zangger uses them extensively in incipient phthisis, but they give excellent results, and naturally prompter ones, in uncomplicated simple bronchitis. They are applied in the following way. A linen bandage about one and one-half inches broad for infants and five inches for adults, and from two to three yards long, is placed in cold water (from 54° to 66°), is well wrung out, and is applied to the chest thus—(1) Beginning under the right axilla, passing over the left clavicle and round the chest back to the right axilla; (2) From here round the chest horizontally; (3) From the right axilla to the left and over the back and the left clavicle to the front (or left axilla). This bandage is covered in the same way with a thick single, or thin double, flannel bandage perhaps half an inch broader. This "pack" is applied at night and left till the morning; on removing it the chest must be well rubbed with a cold, wet towel and then rubbed dry. Several cases are detailed.

The Fixation of Movable Kidney by Means of Strong Carbolic Acid.—T. Carwardine tabulates the particulars of six cases thus treated. His method consists in freely painting the whole surface of the kidney, except the hilum, with the strongest liquid carbolic acid, so that the surface becomes covered with granulation tissue within a few days. The painting is best done after the supporting sutures, etc., have been inserted, but before they are tied, by means of a swab containing the liquid not in excess. In four of the cases—those in which the kidneys were suspended by gauze slings and packing—he has been able to watch the surface of the kidney for from ten days to three weeks afterwards, and he has observed the granulations and lymph rapidly form, followed by intimate and firm incorporation of the kidney with the surrounding tissues. The kidney could then be seen to move with respiration in conjunction with the parts surrounding it, and on pressing upon the exposed renal surface it was found to be inseparably attached even in those cases in which no sutures were used. Moreover, in a case treated thus combined with gauze packing, he was able to verify the results a year afterwards, for on cutting through the old scar for the relief of pain therein of six months' duration, no differentiation of the scar tissue was visible until the cortex of the kidney was actually cut into, so intimate was the fixation. For these reasons, Carwardine is very favorably impressed with Senn's suspension method (with gauze) combined with cortical carbolization. No disadvantages have followed the acid applications and there has been a marked absence of postoperative pyrexia. One patient had temporary hematuria on leaving her bed, which was attributed to tight suturing.

The British Medical Journal, June 28, 1902.

Generalized Vaccinia.—R. W. G. Stewart revaccinated an able seaman who had previously been revaccinated in 1886, and had five typical foveated marks. Four modified vesicles which developed ran a normal course. Three weeks later a rash appeared on the side of the neck and rapidly extended. There were numerous large shotty papules on the left side of the neck, some of which were just entering the vesicular stage. There was no trace of any rash in the vicinity of the vaccination marks or in any other part of the body. The next day the rash was very profuse, and the entire neck was covered with shotty papules and vesicles showing well-marked umbilication. There was at this time a profuse papular rash on both wrists and forearms, the back of the hands and forehead, similar to that on the neck. The next day the rash had become confluent with considerable inflammatory reaction. The axillary glands were enlarged and tender. From this time the rash ceased to extend. Vesiculation and maturation took place rapidly, the process stopping short of the pustular stage. Scabbing became well marked. All trace of the eruption disappeared within a few days. The only symptom complained of was a sensation of heat in the affected parts during the first three days of the eruption. No rise of temperature took place nor were there any constitutional symptoms whatever.

Localized Peritonitis in Typhoid Fever: Laparotomy: Recovery.—W. A. Mackay believes that the early performance of laparotomy in the perforative peritonitis of typhoid fever offers the greatest and generally the only chance of recovery. The patient whose case is reported was a man aged forty-four years. The first attack of the fever was mild, but at the beginning of the fourth week a relapse occurred. There was tenderness in the right iliac fossa, and relative rigidity of the right rectus muscle. In the right iliac region there was a distinct area of dulness on light percussion, and this increased in extent. At the operation this was found to be due to the contracted and empty state of the ileum. There was a fair-sized liver dulness. The abdomen was opened and the lower part of the ileum pulled out. No perforation was discovered, but over a thickened and congested Peyer's patch about six inches from the ileo-cecal valve the peritoneum was roughened and there was an inflammatory exudation. No appreciable fluid exudation was present in the peritoneal cavity. The lower part of the ileum was contracted and empty. From the peritoneal surface there were one or two small reddened portions of bowel evidently corresponding to affected lymphoid tissue, but the portion through which the inflammation had spread was apparently the only patch of size which was affected by the typhoid process. The patch being thickened, no attempt was made to deal with it, save that it was left under the abdominal wound, which was closed by sutures of silkworm gut passing through all the layers. The pulse-rate was never high, but in view of the other symptoms, stress was not laid on this otherwise than as a hopeful factor in prognosis. If patients are to be saved from perforative peritonitis in typhoid fever by means of laparotomy it is certain that many will be operated on in the pre-perforative stage.

Some Phases of Inflammation of the Appendix.—Frederick Treves states that the greater proportion of cases of appendicitis recover spontaneously, and it is probable that the general mortality of the disease—if examples of all grades be included—is not above 5 per cent. Operations carried out during an acute attack are attended with a risk to life which is considerable, and which is probably expressed by a mortality of over 20 per cent. Certain hospital records and collections of cases appear to place the death-rate even higher than this. It must be remembered that relapses may occur after operation carried out during the acute stage. The removal of the appendix during the quiescent period is attended with a very trivial risk, which may be expressed by a mortality of 1 in 500. The writer thinks that our knowledge of the pathology of the disease and its general mortality will not sanction the practice of opening the abdomen in every case of appendicitis as soon as the diagnosis is established. Immediate operation is demanded, at the earliest possible moment, in all ultra-acute cases. These include those very hopeless examples which present from the onset the phenomena of intense infection, and in which it is evident that a very large dose of poison has suddenly been introduced into the system. Death may occur in thirty-six or forty-eight hours. There are also included cases in which the symptoms are as acute as those attending perforation of ulcer of the stomach. The writer noes not believe that these ultra-acute cases are difficult of recognition. Immediate operation is demanded in every instance in which there is reasonable suspicion that suppuration has taken place. In cases outside of those above named, the question of operation may be kept in abeyance for the first few days after the attack, and may usually be left open for decision until the fifth day or after. The great majority of cases of appendicitis recover spontaneously without either an operation or the formation of an abscess; the ultra-acute cases are actually rare, and relatively to the whole mass of examples of all degree suppuration may be said to be uncommon. There are certain cases of adults in which the attack would appear to be led up to by gross deviations from normal food-taking. For example, those individuals who have no teeth, those who "bolt" their food, those who overeat, those who constantly eat indigestible food, and those who neglect their bowels. If these errors be corrected there may be no repetition of the attack. Removal of the appendix is to be recommended in chronic appendicitis, in those cases in which there are no actual attacks, but in which there is abiding discomfort in the right iliac fossa with exacerbations of uneasiness. The removal of the appendix is not a panacea for all ills, nor even for all those manifold pains which seize upon the lower segment of the abdomen.

Deutsche medicinische Wochenschrift, June 12, 1902.

Pulmonary Embolism Following Bone Fractures.—Jacob Putermann reports a case of fractura cruris simplex which was followed by pulmonary embolism. The fracture was reduced and a plaster bandage applied. Eleven days thereafter the patient was moved from one bed to another. Shortly following this he complained of violent pains in the broken limb. These continued, and after six days, on account of the bad position of the limb, the plaster cast was removed and a new one applied. Soon thereafter pulmonary symptoms developed. The diagnosis of infarctus pulmonis dextri ex embolia rami arteriæ pulmonalis was made upon the following grounds: (1) The physical signs in the affected lung in conjunction with an absolutely afebrile condition; (2) Profuse hæmoptysis; (3) Sudden appearance of the symptoms after the movement of the fractured limb; (4) The localization of the process in the right inferior lobe.

Differentiation of Blood by Means of Serum.—Stephen Minovici points out the great value of the precipitin reaction in differentiating bloods of different origin. It has been conclusively shown by Uhlenhuth, Wassermann and Schultze that it is absolutely reliable. Its great practical importance consists in the ability to determine the presence of human blood by its use. The methods hitherto in use for obtaining a suitable specific serum have necessitated the sacrificing of a considerable number of animals because of various infections introduced at the time or shortly after the inoculations. If the abdominal wall is chosen as the site of inoculation and the following technique instituted a powerful serum may be obtained, and very few, if any, animals sacrificed to concurrent infections: By means of sterile scissors the hair is carefully removed from the skin covering the chosen site of inoculation, which is then thoroughly washed with a 2 per cent. bichloride solution. With sterile scissors a slit is then made through the epidermis, into which the needle of the syringe is introduced until its point enters the peritoneal cavity. Upon the withdrawal of the syringe the wound is closed by the means of absorbent cotton and collodion. In obtaining a specific serum for human blood, the blood used for the inoculations should be preferably taken from a vein, all antiseptic precautions being observed. Blood thus obtained gives, upon inoculation, a stronger serum and is much less liable to give rise to concurrent infections than placental blood. In examining dried blood this should be thoroughly macerated in physiological salt solutions and the whole filtered. To 2 c.c. of this clear solution 8 to 10 drops of the specific serum, obtained in the above manner, is added. If the blood is of human origin a precipitation usually takes place in about half an hour at the ordinary room temperature. In many cases,however, a prolongation of this time is necessary for the production of the reaction. In general, it may be said that the older the blood spots, the longer is the time required for the formation of the precipitum. Fresh fluid blood uniformly shows a prompt reaction.

Berliner klinische Wochenschrift, June 16, 1902.

Nephrolysin.—G. Ascoli and F. Figari, as the result of a series of experiments, confirm the results obtained by Lindemann, Nefedieff, and Bierry, and materially enlarge upon the same. The blood of rabbits which have been inoculated with portions of dog's kidneys shows the presence of a powerful nephrolysin. The same, however, cannot be demonstrated in the blood corpuscles, and is exclusively found in the serum. Such serum when inoculated into normal animals at from four to eight-day intervals produces albuminuria, hæmaturia, and cylindruria, which may continue for weeks or months. Similar results may be obtained by the inoculation of the blood serum of animals which have been submitted to unilateral ureter-ligature or nephrectomy. They are, however, of less intensity and duration than those produced in the manner first described. Further experiments show that iso- and auto-nephrolysins possessing a specific elective action are also produced during the process, and that by increasing inoculations of a serum containing nephrolysin an anti-nephrolysin may be produced which, when in sufficient amount, will more or less completely protect the animal against large doses of nephrolysin. These experiments show that the injury or removal of one kidney may give rise to the production of a poisonous product—nephrolysin—which acts as a powerful poison, producing albuminuria, hæmaturia, and cylindruria, and that the organism reacts against such a poison by the production of an anti-body—anti-nephrolysin. The intensity and duration of the above-named symptoms depend upon the power and quantity of the anti-body thus produced.

New Results in the Treatment of Carcinoma by Cancroin.—A. Adamkiewicz reports six cases of carcinoma which have recently been successfully treated by inoculations of cancroin. Of this ½ gm. has been inoculated daily during the period of observation. In all of the cases the improvement was pronounced and began immediately after the initial inoculations. Such an improvement consisted in a reduction in the size of the tumor and induration, together with a marked advance toward health in the general condition of the patient. The first case was carcinoma of the tongue, from which the patient had suffered for three years. The period of serum treatment and observation extends from January 21, 1902, to April 20, 1902. The second case was carcinoma of the epiglottis. Here the inoculations were begun on March 13, 1902. The last date of observation was April 14, 1902. The third case was carcinoma of the œsophagus, which developed during the summer of 1901. Inoculations were begun on March 13, 1902, and the latest observation was on April 26, 1902. The fourth case was carcinoma of the stomach which was first detected in August, 1901. The first serum treatment was given on February 27, 1902, and the last observation was on March 24, 1902. The fifth case was carcinoma of the breast, which first appeared in February, 1900. The period of serum treatment extends from February 17, 1902, to May 2, 1902. The sixth case is the one reported below by Kugel. In most of these cases no local or general reaction was caused by the serum treatment, although in some a marked local reaction followed the initial inoculations. The efficiency of this treatment, the author holds, demonstrates the parasitic nature of carcinoma, upon which theory the preparation of the serum is founded.

Recovery from Carcinoma after Inoculations with the Serum of Adamkiewicz.—L. Kugel reports a case of multiple carcinoma which had been submitted to several operations, but in which recurrence had invariably taken place and further operative procedures were deemed inadvisable. As a last resort, inoculations with the antiserum of Adamkiewicz were undertaken. This treatment was begun in October, 1900, and ½ gm. of the serum (cancroin) was inoculated daily for three months; for the following two months the inoculations were given every second day; from this time until October, 1901, the intervals were increased to from eight to fourteen days. The subjective symptoms began to diminish immediately after the initial inoculations, and after twenty of these the pains and œdema had entirely disappeared. After four months' treatment the tumors ceased to increase in size and the induration began to diminish. Coincident with these changes, the general condition of the patient markedly improved. The general and local improvement thus obtained remained practically stationary up to October, 1901, when, upon the advice of Professor Adamkiewicz, the inoculations were permanently discontinued. During the first weeks of December, 1901, the size of the tumors and the induration began to rapidly diminish, so that at the end of December many of them had entirely disappeared. From this time until May, 1902, there was no recurrence, but a gradual improvement in both subjective and objective symptoms. It is thought that the case has been under observation for a sufficient length of time in order to demonstrate absolutely the efficiency of the serum treatment. With respect to the diagnosis there can be no doubt since the diseased tissue has been repeatedly examined microscopically by experts and pronounced to be of a typical carcinomatous nature.

Münchener medicinische Wochenschrift, June 17, 1902.

Microscopical Appearances of Exhausted Muscle.—W. Scheffer, as the result of a series of observations, shows that under low magnifications exhausted muscular fibers possess a wrinkled appearance which is very different from the smooth aspect of the normal fiber. Under higher magnifications it can be seen that the transverse striations are absent. Under the higher power it is seen that the exhausted fibers have lost their characteristic appearance and have become much thicker and homogeneous in nature. The fibers possess a distinct swollen appearance. These enlargements are arranged irregularly throughout the muscle and are apparently without structure.

Diagnosis of Carcinoma of the Large Intestine.—Friedr. Cramer considers the essential points in the diagnosis of carcinoma of the large intestine. Attacks of intestinal colic occurring at longer or shorter intervals are often the first symptoms of this condition, and when present in supposedly healthy persons, especially those who have passed middle life, they should excite suspicion and lead to a thorough examination for the presence of carcinoma of the large intestine. Of course all cases of this disease are not accompanied by attacks of colic, and such attacks may be produced by other causes, notably the excessive use of tobacco, but their occurrence should always excite grave suspicion as above noted. Rigidity of the intestine upon palpation is one of the most characteristic symptoms of intestinal obstruction. Its presence, of course, does not mean that the obstruction is due to carcinoma. It does, however, signify that the obstruction is of a chronic character, and is one of the most valuable signs in the chain of evidence which is necessary to establish the diagnosis of carcinoma of the large intestine. The location of the rigidity does not correspond with the location of the obstruction, and hence is not available for determining the exact situation of the tumor. So-called stenotic murmurs are of great value in the diagnosis of intestinal stenosis, and it may safely be said that most authors do not attach to them a sufficient importance. These murmurs are to be accurately differentiated from the gurgling sounds frequently heard in various intestinal conditions. The sound most closely resembles that produced by water when it is poured upon the ground at some height from a pitcher. They may be distinctly heard at a distance of several feet from the patient. Persistent tenesmus is very characteristic of carcinoma of the large intestine, and its degree of persistence and intensity throws much light upon the location of the tumor. The lower the tumor is located, the greater is the persistence and intensity of this symptom. The characteristic hemorrhages present in this disease are those in which a small amount of fresh or newly-clotted blood is passed at frequent intervals for a considerable period. Great diagnostic importance attaches to this symptom when careful rectal examination with the speculum has failed to show the presence of hemorrhoids or any inflammatory rectal condition. Under such conditions the presence of pus in the discharges is also of significance. Such pus should always be submitted to microscopical examination, in order to ascertain if broken-down fragments of carcinomatous tissue are present. Much importance has been attached by some authors to the presence of so-called stenotic fæces in the diagnosis of carcinoma of the large intestine. The form of the fæces is dependent upon the condition of the lower rectum and the sphincter ani, only in those cases in which the carcinoma is located low enough to cause an irritation of these structures are stenotic fæces present in this disease. Their value, therefore, as a diagnostic sign is entirely limited to this class of cases.

Treatment of Ulcer of the Stomach.—Wilhelm Fleiner reviews the history of the treatment of ulcer of the stomach, and gives in detail his own method therefor. This consists of the careful carrying out of a rest and diet cure, together with the administration of bismuth subnitrate. The patient is immediately put to bed and all food by the mouth interdicted. Nutrition is administered by the means of nutrient enema. These are given three times daily, and consist of 250 to 300 c.c. of meat broth, to which may be added 50 to 100 c.c. of white wine, one or two beaten eggs or 50 c.c. of milk if necessity requires. This regimen should be continued for from one to two weeks, if possible, and during this time ice should be intermittently applied to the stomach. The lips may be frequently moistened and occasionally small pieces of ice held in the mouth. At the end of this time alimentation by the stomach may be begun. At the commencement this should consist exclusively of milk of which small portions should be frequently given. These should be gradually increased until at the end of two to three weeks 250 c.c. are given every two or two and a half hours. During the latter part of this time, if nutritional demands require, flour, meal, rice, or arrowroot may be added to the milk. At the end of this period oatmeal porridge may be given, and the stomach occasionally naturally irrigated by drinking 100 to 150 c.c. of vichy water. Meat should not be given until after the fourth week, and should at first consist exclusively of the white meat of fowls. Red meat should not be given until after the sixth week, at which time various easily digestible vegetables may be added. The patient must remain in bed until between the fourth and sixth weeks. Even after this time he must assume the recumbent position immediately after eating, and so remain for from one to two hours. This precaution must be preserved following the chief meal of the day for many months. The above treatment brings about a permanent cure in about three-fourths of all cases of ulcer of the stomach. The remaining fourth require in addition a suitable medication. This is to be found in the proper use of bismuth subnitrate. In those cases in which irrigation of the stomach is not contraindicated the following method should be employed: The stomach is at first washed out in the ordinary manner, 10, 15, or 20 grains of the bismuth are then dissolved in 150 to 200 c.c. of luke-warm water, and the whole introduced into the stomach. No food should be taken until at least one-half hour after the bismuth has been introduced. Bismuth may be thus administered daily with advantage. In those cases in which washing of the stomach is contraindicated the bismuth may be given in 10 to 20 grain doses in half a glass of water one-half to one hour before meals. In accordance with the above rules, the author has treated successfully more than 300 cases of this disease. It must, however, be remembered that in many instances the sequelæ of ulcer of the stomach require surgical interference, and that satisfactory final results are oftentimes only obtained when the surgeon has rectified the abnormalities resulting from the ulceration.

French Journals.

Some Remarks on the Régime of Diabetics.—G. Linossier concludes that the régime ought not to be the same in all cases of diabetes. The absolute prohibition of hydrocarbons as food may be more harmful than beneficial. The general restriction of diet, which is often too varied in diabetics, is at least as important in obtaining the diminution of glycosuria as the prohibition of sugar and starches. It is permissible to prescribe a régime much less strict. The benefits of the milk diet, or of the potato diet, are certainly, in large measure, attributable to this restriction.—*Journal des Praticiens*, June 14, 1902.

Tuberculosis of the Epitrochlear Ganglion.—L. Verdelet reports the case of a young man of nineteen years who presented himself with a swelling of the right arm in the epitrochlear region. The family and personal history were negative. There was no apparent port of entry. A little ointment was applied locally for the purpose of resolution, and appropriate general treatment was ordered. On account of the improvement which followed, the patient gave up the treatment. He returned later, however, with the swelling the size of a hen's egg. It was rather painful and slightly movable. There was clearly fluctuation. Besides there were two small swellings in the axilla. Operation was advised. The ganglion was removed and was found to be full of pus. It was tuberculous. Cure followed rapidly.—*Journal de Médecine de Bordeaux*, June 15, 1902.

Ablation of the Tonsils.—George Mahu states that the operation of removing the tonsils piecemeal is not painful, especially if the pieces removed are not too large. All pain will be avoided if the tonsils are first sprayed with a solution of cocaine. This may be followed by an application of adrenal extract, which will do away with the small hemorrhages that are otherwise apt to occur. After the operation the throat should be gargled with hydrogen peroxide. On the day of the operation, and on the day following, the nourishment should be fluid and very cold. The ordinary diet may be gradually resumed. During the five or six days following the operation the throat should be gargled morning and evening and after every meal with the following solution: Resorcin, 10 grams; glycerin and syrup of orange flowers, each 30 c.c.; boiled water, q.s. ad 500 c.c.—*La Presse Médicale*, June 18, 1902.

Intestinal Perforations in the Course of Typhoid Fever.—Ricard reports two cases, the first of which occurred in a patient of Akopoff's, while the second case was his own. The first patient was a man of forty-three years. On the twentieth day of his fever he exhibited the symptoms of perforation. Laparotomy was performed thirteen hours after the perforation occurred, and the lesion was found to be 40 cm. from the ileocæcal valve. In the second case intervention took place fifteen hours after the accident. The symptoms were not so severe as they are ordinarily; there was a little distention of the abdomen, pain and fever; the general state was not alarming, but the abdomen was opened, and a mass of intestines was found glued together. On separating them, several small perforations were found that had been closed over by the matted intestines. One larger perforation was in the process of healing. In both of these cases the perforations were sutured and good results followed.—*Le Bulletin Médical*, June 21, 1902.

The Journal of Tropical Medicine, June 16, 1902.

Peculiar Markings of the Tongue in Ankylostomiasis.—Percy H. Delamere some time ago began to notice that all the patients under treatment for this disease had a peculiar mark on the tongue, exactly as if the patient had just wiped a penful of blue-black ink on his tongue. Further observation showed that all patients who had passed ankylostomes after treatment had more or less marked tongues. Further than that, the examination of the tongues of a number of apparently perfectly healthy coolies without anæmia nor any sign of disease, showed the blue-black marks, and after the administration of thymol every one of them passed mature ankylostomes. If this is a regular symptom of the disease, it is well worth making public, as the author believes it to be an early sign, before there is pronounced anæmia, and of such easy diagnosis that cases can be treated and cured before there is much damage done. Illustrations of the markings accompany the article.

Quinine Idiosyncrasy Leading to Hæmoglobinuria.—Aubrey Hodges describes the case of a patient who had heard of Koch's theory of the relation of quinine to blackwater fever, and had therefore carefully abstained from taking the drug. On one occasion when he did so he passed black urine a few hours later. After that he took methyl blue as a substitute for the quinine, of which he had so great a horror that he could not be persuaded to try it. The writer mixed half a gram of quinine sulphate with the patient's morning nutrient enema without his knowledge, and as no bad result followed, except the passing of port-colored urine on one occasion only, increased the dose to half a gram twice daily, without recurrence of hæmoglobinuria, and with distinct benefit to the patient. The latter was then told that he had been taking quinine daily, and has lost all fear of the drug. He has had two subsequent attacks of malaria, during which he was freely dosed with quinine without any recurrence of hæmoglobinuria.

Sterilizing Edged Eye Instruments.—Instruments should be wiped and placed in the tincture for fifteen minutes, then wiped again and placed in boracic-acid solution before the operation. After use they should be replaced in the tincture and wiped and put away. This not only cleans off blood and pus, but preserves the edge.

Therapeutic Hints.

Infantile Diarrhœa. The keynote to the management of these cases is the complete elimination or cleansing of the gastrointestinal canal of all bacteria as far as possible, as well as that which generates bacteria; absolute rest and quiet, giving sterilized food, and strict attention to the smaller details. C. L. Lawless.

Chronic Otitis Media. Installations into the ear of fifteen to twenty drops of a 2 per cent. watery solution of methylene blue, after a preparatory cleansing of soap and water, diminishes the purulent discharge and controls the fetid odor in the chronic otorrhœa of children. H. Gaudie.

In Peritonsillar Suppuration.—Equal parts of carbolic acid, menthol, and cocaine, to which a few drops of alcohol are added will produce local anæsthesia along the line of intended incision. John J. Kyle.

Burns. A saturated solution of potassium permanganate is recommended as an application for burns. It diminishes pain very markedly and causes a rapid healing of the wound. Kharitonov.

Rheumatic Gout.—Jonathan Hutchinson considers the salt pack the most effectual remedy for getting rid of the irritation and synovial effusion of rheumatic gout. A flannel soaked in a saturated brine of common salt is wrapped around the affected joint, covered with oiled silk and a bandage, and kept on over night.

Loss of Voice from fatigue or simple laryngitis is relieved by small doses of nitric acid well diluted and given every two hours. Bartholow.

For Gunpowder Stains of the face, a cloth saturated with a 50-per-cent. solution of hydrozone is very efficient. Corbett.

In Pulmonary Œdema a one-fiftieth of a grain of strychnine and a one-hundredth of a grain of atropine injected beneath the skin below the clavicle, repeated according to indications, will relieve and save many cases. C. Donovan.

Treatment of Ophthalmia Neonatorum.—Edward Lander (*Cleveland Medical Journal*) states that treatment must be energetic regardless of the tender age of the patient. The first indication is to keep the conjunctival sac free from pus, and this is best accomplished by the frequent use of a sterile salt solution, a 3 per cent. solution of boric acid, a 1 to 8,000 solution of formalin, or a 1 to 15,000 solution of bichloride of mercury. Pledgets of linen or cotton, laid on a cake of ice, should be applied and changed every one or two minutes. Cold should be discontinued when the swelling of the lids diminishes, or when the integrity of the cornea is threatened. The best germicides for the destruction of the microorganism are a ½ to 2 per cent. solution of silver nitrate, a 20 to 40 per cent. solution of protargol, formalin 1 to 3,000 and bichloride 1 to 5,000.

In Opium Narcosis first empty the stomach with stomach tube to prevent further absorption; then give a cup of strong hot coffee. The latter allays nausea and acts as a physiological antidote. Keep the patient aroused by walking and the application of water, and give atropine sulphate, gr. 1-50, and strychnine sulphate gr. 1-30, hypodermatically. J. J. Peterson.

The Time to Operate in Appendicitis.—In the early hours of an attack, preferably the first twelve, insist on operating, provided a competent surgeon is to be had, and tell the patient that an early operation by a competent surgeon is practically safe, but that the non-operative treatment is safer in any event than operation at any time by a surgeon of doubtful ability. Christian Johnson.

Treatment of Infantile Paralysis.—Dr. James Taylor (*The Hospital*) divides treatment into that which is required at the outset and that which is employed later on. At the time of the attack treatment must be conducted on general lines, as if one had to deal with a general febrile disturbance, care being taken not to overlook a commencing infantile paralysis in a child with high fever and pain in the limbs. There is no specific, but salicylate of soda relieves pain in the early stages. Later on massage and passive movement favor the nutrition of the muscles and tend to prevent contractures. Electricity, though important, is less so than massage; it gives exercise to the muscles. The constant current should be employed. Though treatment of this condition is limited, it is essential that it should be carefully carried out.

Enlarged Bronchial Glands in Children.—These patients are best treated as one would treat phthisical subjects, namely, by forced feeding, careful regulation of the diet and hygiene, plenty of fresh air, and guaiacol and cod-liver oil internally. For the spasmodic cough, which is a source of great annoyance and irritation, thirty drops of creosote, with or without the addition of menthol, burnt on a hot shovel in the patients' room at night, gives very beneficial results in most cases. D. McM. Officer.

Rhythmical Head Shaking in Aortic Patients. Charles Valentino reports fourteen cases of Musset's symptom, of which one occurred in pleurisy, eight in aneurysm of the arch of the aorta, and five in aortic insufficiency. He considers that the case of pleurisy is not perfectly established, and that the symptom is still to be considered as belonging exclusively to aortic affections. It has not as yet been determined whether the sign is systolic or diastolic. The author agrees with Delpeuch, that the presence in aortic patients of this new symptom, which is certainly rare, but very well marked and striking when it does exist, should constitute an indication of a grave lesion, which, until the appearance of the symptom, has been either latent or unperceived.—*Revue de Médecine.*

Society Reports.

THE PRACTITIONERS' SOCIETY.

172d Regular Meeting, Held on Friday, May 2, 1902.

Joseph D. Bryant, M.D., President, in the Chair.

A Case of Bullet Wound of the Brain Followed by Epileptic Convulsions; Operation.—Presented by Dr. Robert Abbe. The patient was a young man who, in 1885, was shot in the head, the bullet entering just above the left eye. The ball was of small caliber, and did not give rise to any symptoms until seven years after the accident, when the man began to have convulsions, which gradually increased in frequency, sometimes as often as six a day. When he came under Dr. Abbe's observation, two radiographs were taken, one lateral and one front view, which clearly showed the bullet imbedded in the brain. An operation was thereupon undertaken for its removal. Upon opening the dura, a cyst about the size of a large marble was found pressing upon the brain. After evacuating this and dissecting out the cyst-wall, an effort was made, with the radiograph as a guide, to locate the bullet. The brain was probed at the apparent site of the bullet by a steel pointed probe attached to the Girdner telephone. The needle was inserted about forty times, but it failed to detect the bullet, and it was deemed best not to incise the brain.

Subsequent to the operation, there was no immediate improvement in the man's condition, but gradually his convulsions abated in frequency, and during the past six months he has had none at all. The man is still taking bromide in small quantities. Dr. Abbe said the subdural cyst was probably the cause of the convulsions in this case, and not the bullet. An interesting feature of the case was that in spite of the fact that the bullet was beautifully shown in the *x*-ray picture, it could not be located by very thorough probing. This was possibly due to the deceptive deflection of the rays, though a firm capsule of the encysted bullet might have prevented metallic contact with the needle point. The cyst could not be made out in the radiographic picture.

Dr. Abbe said this was the fourth time he has had occasion to use the telephonic probe, but it had never proven of assistance to him in locating an encysted bullet. In every case he had made a control test with a similar bullet fresh laid in the wound to prove the perfect working of the beautiful mechanism of Girdner's telephonic probe.

Dr. George L. Peabody said that as an illustration of the uncertainty of the probe in bullet wounds of the brain he recalled a case which came under his observation some years ago. The patient was a man who was shot in the forehead, and it seemed quite possible to get a very definite idea of the direction of the ball from the angle at which it had been fired. The surgeon who had charge of the case inserted a probe, and claimed that while he was unable to locate the bullet, he could readily follow its track entirely through the brain to the occipital region. The patient died and at the utopsy it was discovered that the bullet had merely perforated the frontal bone, not even penetrating the dura; it was found just inside the skull about a quarter of an inch from its point of entrance.

The President, Dr. Bryant, said that some years ago he saw a case of bullet-wound in the temporal region, and he was unable to locate the ball until he adopted the following expedient: He introduced a large probe directly into the track of the bullet, and carried it backward until it struck the cranium on the opposite side; he then took a piece of string and described several meridians corresponding to the external portion of the probe around the skull; a trephine opening was then made at the point where these lines crossed each other at the opposite side. Through this trephine opening the probe which had been passed through the brain came directly out and the bullet was found.

In operating for the removal of foreign bodies which have been located by X-ray pictures, Dr. Bryant said he had found much assistance and had been entirely successful by using needles as a guide. For example, in a case of foreign body in the wrist, he divided the region into quadrilateral spaces by means of cambric needles passed through the skin before the picture was made. By this method he learned exactly where the foreign body lay, and in which of the spaces to make his incision. The depth of the foreign body in the tissues was determined by taking a picture of a side view of the limb.

Dr. Bryant said that one drawback he had met with in using the telephonic probe was the repeated alarms produced by the particles of metal which are apt to be left behind by a bullet passing through a bony structure. He regarded Dr. Girdner's probe as an excellent apparatus. In Dr. Abbe's case, the cyst was probably the exciting cause of the convulsions rather than the bullet.

Pancreatic Lithiasis, with Report of a Case.—Dr. F. P. Kinnicutt said he had already reported this case at the meeting of the Association of American Physicians in Washington. The patient was a woman, aged forty-two years, whose family history was unimportant. In 1888 she had suffered from the first attack of pain in the right, hypochondrium, associated with nausea and vomiting. There were two other attacks, one in 1897 and the other in 1898. Then there were no more until 1901. This attack was very severe. On the sixth day six small calculi were passed in the stools, and analysis of four of the concretions, showing them to be composed chiefly of phosphate of lime, pointed to their origin in the pancreatic duct. The patient had first come under Dr. Kinnicutt's observation on December 25, 1901. Specimens of both biliary and pancreatic calculi passed by this patient were obtained and were exhibited. Cultures made from the central portion of one of the recently passed calculi gave no growth. Repeated examinations of the urine failed to show the presence of sugar. The weighing of the fat ingested and excreted showed normal fat absorption. The presence of an unusually large number of striated muscular fibers in the stools, the speaker said, could not be regarded as of much diagnostic importance. The presence of fat in the stools was often due to the coexistence of jaundice, and its consequent interference with the digestion of fat. A deficient splitting up of the intestinal fat into fatty acids and soaps was, on the other hand, apparently a symptom of great importance. The absence of glycosuria could only be regarded as a negative sign in connection with pancreatic lithiasis, though its presence was a suggestive sign. The absence of a cachexia or other signs of a malignant disease of the pancreas in the case reported, and the presence of the other signs and symptoms detailed, seemed to warrant the diagnosis of pancreatic lithiasis. Dr. Kinnicutt said that literature gave only six cases in which a positive diagnosis of pancreatic lithiasis had been made or the condition suspected during life.

Dr. Beverley Robinson said he had at present under his observation a patient in whom he suspected this rather rare condition of pancreatic lithiasis. There have been several attacks of pain in the right hypochondrium, the first one occurring about three or four months ago. There is some abdominal distension, but the patient has never been jaundiced. Biliary colic has also been suspected, and there is a possibility that there is a calculus in the cystic duct. The patient's stools have been examined by Dr. Soudern, who reports that they do not contain any calculi or an excessive amount of fat; he found, however, an unusual quantity of muscular fibers and a trace of blood.

Dr. W. Gilman Thompson said that if the case reported by Dr. Kinnicutt had not been so exhaustively studied, it could easily be mistaken for one of gall-stones, and it leads one to inquire whether this condition of pancreatic lithiasis is not more common than the limited records would suggest. Many cases of supposed gallstone are operated upon in which at the time of operation no stone can be found, and this study should emphasize the importance of carefully examining, in such cases, the pancreas, in view of the possibility that one is dealing with pancreatic calculi instead of gall-stones.

Dr. **Peabody** asked if it is possible to examine the pancreas successfully for the presence of small stones like those found in the case reported by Dr. Kinnicutt.

Dr. **Bryant** said he would regard the result of such an examination as very questionable. It could hardly be relied upon as a certain element of diagnosis.

Dr. **Peabody** said that in advanced diabetes he has found, at autopsy, well-marked pancreatic lithiasis associated with an atrophied condition of the pancreas. He recalled one case where the pancreatic duct was so completely occluded that the condition resembled a plaster of paris cast. In none of his cases had the stones given rise to any symptoms during life, so far as the history of the patients disclosed.

Dr. **Kinnicutt** said that in one of his cases, where pancreatic calculi had existed for a considerable period, the condition was associated with a suppurative pancreatitis.

The speaker said it has been exceedingly difficult to get any definite information as to the frequency with which calculi are found in the pancreas. Only about fifty cases have been reported in which calculi of the pancreas were found at autopsy. Unless a very careful examination of the pancreas is made, the small, gritty particles, composed of carbonate and phosphate of lime, might easily escape detection. He had been rather surprised to learn that fatty stools were so frequently absent in pancreatitis. Among 330 cases, they were only present in twenty-eight. It is not the absorption of fat that is in any way interfered with in this disease, but the splitting up of the fat, and this point should be regarded of importance in the diagnosis, rather than the mere presence of fat in the stool. The absorption of fat is enormously interfered with in the absence of bile, but not when there is an absence of pancreatic juice.

Removal of the Cervical Sympathetic for Optic Atrophy in Tabes. Function of the Cervical Ganglia of the Sympathetic.—Dr. **Charles L. Dana** said that physiologists, basing their conclusions mostly on animal experiments, give rather less importance to the cervical sympathetic than do clinicians and pathologists. Thus, Dr. Langley, in Foster's Physiology, states that stimulation of the cervical sympathetic causes: (1) Dilatation of the pupil; (2) Retraction of the "nictitating membrane"; separation of the lids and protrusion of the eyeball; (3) Contraction of the blood vessels of the skin and mucous membrane, and of the salivary and other glands; (4) Dilatation of the blood vessels of the bucco-facial region of the dog; (5) Decreased secretion from all the glands; lachrymal, salivary and mucous; (6) Erection of hairs. Section of the cervical sympathetic causes: (1) Dilatation of blood vessels, marked in skin, ear and conjunctivæ, and in the mucous membranes; doubtful in brain; (2) Rise of temperature; (3) Decreased secretion; (4) Narrowing of palpebral fissure and retraction of eyeball. These effects disappear in three or four weeks. Destruction of the sympathetic in man has been observed to be followed, in addition, by: (1) Lessened tension of the eyeball; (2) Hemiatrophy of the face; (3) Bradycardia in rare cases (usually no effect on the heart); (4) Headache, nervousness and cephalic pressure. Late experiments have shown possibly some increase in retinal vascularity, and (in dogs and cats) some trophic changes in the retina and eyeball. Any marked effect on the vascularity or activity of the thyroid gland has not been established. Extirpation of the cervical sympathetic has been attempted: (1) For epilepsy; (2) For Grave's disease; (3) For glaucoma and atrophy; (4) For optic atrophy of tabes dorsalis. There is no justification for attempting it in epilepsy, and the results have been poor. The operation has no standing. In Grave's disease some improvement has resulted, mainly in the exophthalmus. In glaucoma a good many operations had been done often with temporarily good results.

In the *Journal of the American Medical Association*, for June, 1900, Dr. J. M. Ball reported a case of simple optic atrophy (of tabes?) in which he removed the superior cervical ganglion on the right side. The patient was a man forty-six years old, with total blindness in the left eye and perception of light in the right. There was advanced atrophy in both eyes. The result of the operation was practically negative, although a slight enlargement of the cilioretinal artery was noticed. On November 23, 1899, Dr. George F. Suker removed both superior cervical ganglia in an advanced case of simple optic atrophy. The perception of light and form and the visual field were all increased after operation. This case was reported in the *New York Medical Journal*, 1900, page 267. Recently Dr. Dana had a patient with tabes and optic atrophy referred to him by Dr. John L. Adams. He had advised removal of all three cervical sympathetic ganglia on the least affected side. This had been done by Dr. Frank Markoe. The patient, a man about fifty, was in the first stage of tabes; the optic atrophy moderately advanced, but he could still read large type. The tests for visual aciuty and field, taken before and two or four weeks after operation by Dr. Cutter, Dr. Adams and himself, showed distinct improvement in vision and enlargement of visual field. There were the usual narrowing of the palpebral fissure, contraction of pupil, and anidrosis on the operated side.

Dr. Dana had under care another case of optic tabes with advanced atrophy. He had been under Dr. Gruening's care and had, at that time, had the upper cervical ganglion removed by Dr. Gerster, with no improvement. Dr. Markoe's operation was the first in which all three ganglia had been removed, viz., for tabetic atrophy, and it had apparently produced the best results.

The speaker had always regarded the cervical sympathetic as a somewhat superfluous organ, whose functions were readily dispensed with or assumed by other parts. Still, some very positive results had been claimed in Graves' disease and glaucoma. In optic tabes the outlook is so hopeless that we grasp at any measure that may by any possibility give relief.

Dr. **Charles Stedman Bull** said that so far as it concerned glaucoma, the operation of resection of the cervical sympathetic, or sympathectomy, as it was called, was still *sub judice*. The operation was suggested by two very competent men, who are known to be of rather enthusiastic temperament. The number of cases on record thus far is still too small to allow any definite conclusions to be drawn. The operation is indicated only in simple, chronic glaucoma. Dr. Bull said he had done the operation in two such cases; one about a year ago, the other two months later. In both of these cases the patients had declined an iridectomy. In both the operation was followed by evidences of increased circulation in the optic nerve, but this improvement was only temporary, and both the patients are now going on towards total blindness. The most that can be said for these cases is that the operation produces a temporary, and, at times, a decided visible and demonstrable increase in the circulation of the optic nerve, with apparent arrest of the symptoms and the maintenance of existing vision. In the cases which have been long enough under observation, there has been, after a time—sometimes as long as a year after the operation—a reappearance of the disease, with an increase of the symptoms. The intraocular tension is decidedly diminished within an hour after the operation.

Dr. Bull said that in the future he would perhaps feel inclined to do this operation in the cases where iridectomy is declined. In many of the cases reported, only a transient benefit followed the operation, the disease again following its regular course, much the same as is not infrequently seen after iridectomy. The speaker said that in one case where he did an iridectomy, fourteen years ago, the vision then existing is still the same to-day, but such a result is exceptional.

Dr. Abbe said that some three years ago he removed the greater part of the right cervical sympathetic from the base of the brain down to the mediastinum, because its involvement in an extensive fibro-neuroma which was composed of a chain of glands ranging from the size of a bean to that of a hen's egg. That portion of the cervical sympathetic below the mediastinum was also involved in the growth, but could not be removed. Dr. Abbe said that this case, which he reported at the time, was almost unique. ("Large Multiple Neuro-Fibromata of the Cervical Sympathetic," *Annals of Surgery*, April, 1898.) The patient's health was apparently not affected in any way by the removal of the cervical sympathetic; there was no hemiatrophy of the face, nor other symptoms. Since the operation, there has been a slight similar growth in the glands on the opposite side without deterioration of health.

The Ultimate Result of Beatson's Operation.—Dr. Abbe said that at a meeting of the Society one year ago he presented seven patients upon whom he had performed oophorectomy, as suggested by Beatson, for inoperable or recurrent cancer of the breast. As the result of a careful observation of these cases for one year, the speaker said he was able to report (as he had then promised the Society) that, in the majority of instances the operation produces a temporary retrograde metamorphosis in the diseased tissue and adjacent glands. This improvement lasts, upon an average, about four and one-half months; then the disease usually takes on renewed activity and pursues its regular course. Of the seven cases reported a year ago, Dr. Abbe said that four had died. In the remaining three he is now using the *x*-ray with even more striking results than were obtained by the Beatson operation. In connection with the report of these cases, Dr. Abbe showed a number of colored plaster casts of malignant mammary tumors, illustrating the effects of his treatment by raidotherapy, not only in recurrent but in primary cancerous tumors of the breast and other parts. A year hence he felt we could have a similar report of results which would give a fair estimate of its value—as judged by time. At present he can only say that the outlook has more of promise than any therapeutic method—outside of pure surgery.

Dr. Peabody said the Society owed Dr. Abbe a debt of gratitude for his report upon the value of the Beatson operation after having investigated a sufficient number of cases to justify him to generalize in regard to it. The speaker expressed the hope that the results of the *x*-ray treatment in cancer of the breast would be equally satisfactory and more lasting.

Dr. Abbe, in reply to a question as to the value of the *x*-ray in cancer of the internal organs, said that he had employed the treatment in two cases of cancer of the stomach without any apparent benefit.

Dr. Clement Cleveland said that in the treatment of recurrent or inoperable cancer of the breast, he thought the use of the *x*-ray was more promising than Beatson's operation, especially in those women who have passed the menopause. As an illustration of the apparently marvelous effect of the *x*-ray upon cancer elsewhere in the body, the speaker reported the following case: The patient was a woman, over fifty, with a cancer of the uterus, which Dr. Cleveland removed by vaginal hysterectomy three years ago. The vaginal opening healed rapidly and the result was apparently very satisfactory. During the first year the patient reported at his office every three months; then at less frequent intervals. Up to eighteen months after the operation the whole vaginal vault remained apparently normal, but at the woman's next visit she said that she had suffered from a little bleeding. Examination showed a small ulcerated spot at the seat of the vaginal scar, which was cauterized and healed within a week without any resulting infiltration. After three months this area of cicatricial tissue broke down again and was again cauterized. This was repeated several times, until finally the ulceration failed to heal in spite of repeated cauterizations. Her family physician then suggested the use of the *x*-ray, with which he had been experimenting. That treatment was thereupon used and, as a result of it, the ulceration has entirely healed, the induration has disappeared and the vaginal vault is again perfectly soft and apparently normal. The *x*-ray certainly produced a curative effect in that case

Specifics in the Treatment of Disease.—Dr. Peabody said he wished to make a preliminary report in connection with Dr. Andrew H. Smith's recent paper on this subject. The speaker said that during the past two months he had treated twelve cases of pneumonia by aspirin with very gratifying results. The drug was given in doses of fifteen grains four times daily. In some of the cases only one lung was affected, in others both. Some of them were accompanied with active delirium and one with alcoholic delirium. All of them recovered, and in every instance the disappearance of the fever was by lysis. In one of the cases the pneumonia complicated typhoid fever.

The drug apparently had a marked effect upon the course of the disease, usually causing a rapid subsidence of the pain and dyspnœa. In its effect it resembles other forms of salicylic acid. As it does not undergo resolution until it reaches the duodenum, it rarely produces any stomach symptoms, as the more soluble preparations of salicylic acid do. It apparently does not readily cause head symptoms, although one is justified from its composition in supposing that such symptoms would occur if the dosage were sufficiently large.

THE AMERICAN PEDIATRIC SOCIETY.

Fourteenth Annual Session, Held at Boston, Mass., May 26, 27 and 28, 1902.

First Day, May 26.

President's Address. — Development the Keynote of Pediatrics.—Dr. W. S. Christopher of Chicago said that pediatrics had more possibilities of usefulness, greater unexplored domain, and dealt with more fundamental biological truths than any other department of medicine. Pediatrics was a part of general medicine, but general medicine as taught and practised was free from active interest in the subject and had many important omissions. The fact that pediatrics was preventive medicine of the highest order was possible because the developmental period of human life could be acted upon strongly by environment. The higher the intelligence of adult animals and the more complex its life activities the longer the period of development. As the number of experiences in the life of the individual increased more nerve connections must be established to control them. Finally, in course of development a time was reached when necessary nerve connections could not be established before birth, but were partly established by education after birth. This gave rise to a period of infancy. The course of natural development, the pathological conditions resulting from deviations from this course, and the influence of enivronment were factors of sufficient import to create the subject of pediatrics. The President requested the members of the Society to favor the establishment of a laboratory at Washington, by the Department of the Interior, for the study of the criminal and pauper classes, as by this means most valuable data could be obtained referable to the development of the child.

Intussusception: Clinical Remarks.—Dr. F. Huber of New York said that early recognition of the lesion and knowledge of the limitation of methods of injection and inflation were essential to success in the treatment of acute intussusception. He reported the following case. Male child, eight and a half months old, weighing nineteen pounds, previous health good, no history of trauma. The child had a sudden attack of diarrhœa, not accompanied with vomiting or pain. Four hours later became suddenly restless and refused to nurse. A few hours later there was evidence of severe paroxysmal abdominal pain, accompanied with incessant vomiting. The abdominal wall was soft, relaxed with a slight swelling in the region of the transverse colon. A high rectal enema was given with hips elevated, which was followed by a bloody mucous discharge resembling currant jelly. The tumor disappeared, but as no feces escaped, partial reduction was thought to have taken place. The case was seen by Drs. J. F. Erdman and H. M. Silver. An abdominal section was performed, the mass reduced, and the child recovered. Dr. Huber said that Edmund Owen (*British Medical Journal*, September 7, 1901), based a diagnosis on the following conditions: Sudden abdominal pain, vomiting, passing of a stool with much straining containing blood and mucus, and the presence of a tumor, usually in the ascending colon. Injection was advocated to reduce the invagination and lessen the size of tumor, and so decrease the field of operation, but should be employed only during the first twenty-four hours of the attack. The disadvantage of the injection was dependent upon the impossibility to gauge the amount of pressure, inability to exclude beginning gangrene and the fact that the reduction is not always complete.

Intussusception: Surgical Comments.—Dr. John F. Erdman of New York said that operation for intussusception was accompanied by far less mortality than when hydrostatic pressure and inflation were practised. After twelve hours surgical treatment should be considered the only treatment. Shock called for more rapid reduction and should not be considered a contraindication for operation. In reducing the invagination, traction on the proximal end was apt to cause a tear; pressure should be made on the apex of the mass at the distal extremity.

Healed Septic Endocarditis. Dr. Samuel S. Adams of Washington, D. C., referred to his service at the Children's Hospital of that city and said that this affection had been considered rare in children, but he thought the frequency had been underestimated, a fact probably due to difficulty in diagnosis. Osler had reported 209 cases, only three being under three years of age. The disease had been considered to be of two varieties, but the concensus of opinion to-day was that the difference was of degree rather than of kind. The history of a case with recovery of a child six years old was given. In the discussion Dr. Jacobi thought that these cases were caused by the presence of bacteria or of toxins. In those cases termed malignant, there were bacterial deposits on the valves. Cases caused by toxins were apt to get well because the toxin eventually exhausted itself or was eliminated.

A Case of Chondrodystrophy Fœtalis.—Dr. John L. Morse of Boston reported the case of a boy who died at the age of four months. When seen at two months he weighed six pounds and was of average intelligence. The legs were short, otherwise the child was normal. Dr. Morse said that little was known as to the cause of the disease, hereditary influence probably playing an important rôle. Most cases died in youth; mild cases might reach maturity. In the discussion, Dr. J. P. C. Griffith of Philadelphia reported two cases which he considered chondrodystrophy fœtalis. The cases had curious paddle-shaped hands and feet. Dr. Holt of New York, reported a case four years old, in which he used thyroid extract almost continually for about two years without appreciable progress.

The Management of Rheumatic Children.—Dr. F. M. Crandall of New York read this paper. He called attention to the frequency of the distribution of symptoms through months and years, and that same symptoms, habitually found in children, were rarely seen in adults. The management was considered under four heads: Clothing, exercise, diet, and medication. Flannel should be worn all seasons of the year—thin in summer. Exercise and outdoor life should receive particular attention. The diet should be generous and nourishing, for there was a marked tendency to anæmia. The trend of opinion was of restriction of sugars and starches. By the use of salicyl compounds, much could be done to prevent acute outbreaks by administering small doses three times a day one week of every month of the year. The object of active treatment should be to control fever, relieve pain, check the arthritis and other local symptoms by neutralizing the effect of the rheumatic poison on fibrous structures, and to prevent involvement of serous structures, especially the heart. Referring to the alkaline and the salicylic methods of treatment, Dr. Crandall said that large doses were required at the outset in either method, and that both were prone to disturb the stomach and depress circulation. The selection of one treatment or the other should be made and adhered to as chief treatment.

The child should be given a cathartic in beginning treatment; calomel was to be preferred, salines having a tendency to increase anæmia in children. In the experience of Dr. Crandall, sodium salicylate had proved the most satisfactory drug; he gave 40 grains a day to a child six years old in 5-grain doses every three hours. The interval was reduced after three days, if the disease was under control, but during the first three days the drug should be given at regular intervals both day and night. As a rule the drug was not well borne on an empty stomach. Hyperpyrexia could be controlled by cold baths or cold packs, or small doses of phenacetin well guarded with a stimulant. Anæmia developed rapidly in rheumatic children, therefore iron should be given early, as soon as the temperature was below 100°. A generous diet should be given as soon as possible. As to local treatment, the joint should be protected from air by a flannel bandage or cotton wool, a light splint frequently added to the degree of comfort. Heat was more acceptable than cold. Oil of wintergreen sometimes gave good results, but the odor soon became objectionable. A child suffering from any rheumatic manifestation should be put to bed and kept between blankets until all evidence of the affection disappeared. This would do much to prevent cardiac involvement.

Typhoid Fever in Children Under Two and a Half Years of Age.—Dr. J. P. C. Griffith of Philadelphia said that more detailed study would tend to eliminate the difference of opinion which existed on this subject. A wrong impression was conveyed by the statement that typhoid fever in infancy (under two years) was rare, and several cases were reported to prove this. Cases under three months were revealed at the autopsy and not recognized during life. Statistics were read in support of this statement. In the discussion Dr. Morse thought that typhoid fever was rare among infants in Boston. Dr. Holt said that there was insufficient evidence to show that typhoid fever was common in infancy.

Typhoidal Appendicitis in Children.—In presenting this paper, Dr. A. Seibert of New York said that the subject of typhoid fever in children had been somewhat neglected. Two cases of typhoidal appendicitis were reported. The first case of a boy, aged eleven, in which a diagnosis of typhoid fever had previously been made. The child was suddenly seized with severe abdominal pain in the right iliac region; temperature rose to 106°. Later an ulcerated appendix was removed. The indications of typhoid fever disappeared in two weeks. The wound discharged pus freely for about five weeks. (Charts were shown giving temperature variations.)

SECOND DAY, MAY 27.

Report of a Case of Extreme Enlargement of the Spleen with Anæmia; Autopsy.—Dr. S. McC. HAMILL of Philadelphia reported this case. Child six years old, family history negative; had frequent profuse epistaxis, severe gastric pains for several weeks, accompanied by hæmatemesis; blood was passed from lower bowel; there was marked prominence of the abdomen. By palpation a huge firm mass could be made out in the upper left abdomen. Urine examination was negative. The child was well for over a year following this attack; a second similar attack resulting in recovery occurred nineteen months later. One year later a third attack proved fatal. The autopsy, limited to the abdomen, showed a large spleen, seven by four inches, pancreas imbedded in fat, and kidneys larger than adult organs, exceedingly pale on section.

A Case of Venous Thrombosis Resulting in Extensive Cerebral Hemorrhage in an Infant Fifteen Days Old.—This case was also reported by Dr. S. McC. HAMILL. A specimen of fusion of the kidneys was shown, an accidental finding at the autopsy.

Presentation of Cases of Tuberculous Peritonitis.—Dr. T. M. ROTCH of Boston, presented six cases in which an abdominal section had been performed, giving a brief history of each case. He said that the operation was simple and gave good results when performed by a skilled operator. Tuberculosis of the mesenteric glands and peritoneum should be considered an indication for laparotomy. Of twenty patients that had come under his observation, eighteen were alive and apparently healthy two to five years after operation. Dr. Rotch said that the patient should be given the benefit of the doubt and a laparotomy performed, especially as the operation was practically harmless.

In the discussion Dr. FORCHHEIMER of Cincinnati said that while laparotomy when properly performed was generally without danger, it was difficult to select proper cases for operation.

Dr. KOPLIK of New York thought that the percentage of recoveries was about the same whether an operation was resorted to or not. If the child improved with hygienic treatment operation should not be resorted to.

Dr. JACOBI of New York said that as long as the tuberculous process was localized the child was likely to recover, no matter what was done, unless the surroundings were unfavorable, when the disease was apt to progress. A localized process was not usually characterized by fever. He recommended cod-liver oil in winter, guaiacol in summer, the iodide of potassium or sodium as adjuvants to rest, air, and good food. When the process was disseminated no treatment would avail after one or two years' standing; results seemed to be about the same whether operation was resorted to or not.

In closing the discussion Dr. Rotch said that it was not good practice to resort to operation as a last hope, especially in view of the lack of danger associated with laparotomy.

The Use of the Term Enanthem.—Dr. F. FORCHHEIMER of Cincinnati read this paper. He said that the term had been adopted by the French in 1882, later by the Germans, and was growing in use. He recommended this term for the following reasons: (1) It was etymologically correct; (2) It had been adopted by other nations, and there should be a tendency to make medical nomenclature international; (3) Time was saved by its use; (4) Precision was gained in definition, and as the term would be applied to eruptive fevers the connection would always preclude any doubt as to meaning.

Some Remote Diseases Arising from Tonsillar Infection.—In presenting this paper Dr. FORCHHEIMER said the fact that the tonsils might be the seat of infection in remote parts had been known for some time. Among such possible infections were recognized diphtheria, erysipelas (Gerhardt), tuberculosis (Baumgarten), pneumonia, scarlatina and measles (Menzer). Bacteria were not frequently found in the tonsils, a fact which might be due to rapid blood current, active phagocytosis, or resistance of endothelial covering of the tonsil (Hodenpyle). If bacteria passed through the wall of the tonsil they might be expected to be present at the next barrier, namely, the lymph nodes at the angle of the jaw. While these nodes received lymph from the root of the tongue, the nose and pharynx, as well as from the tonsils, it was true that in most every case of tonsillitis the lymph nodes at the angle of the jaw became enlarged; this would suggest the possibility of bacteria being taken up by the tonsils. From this portal of entrance, bacteria were carried to the general circulation in the lymph or blood. Dr. Forchheimer quoted Stillman, Courmont and others to show that bacteria had been found in the blood. The only remaining factor necessary for remote infection was a *locus minoris resistentiæ*. Remote effects might also be produced from toxin absorption. A case of typical angina tonsillarum, followed by appendicitis, was reported.

A culture showed the presence of the staphylococcus albus and the streptococcus. The amygdalitis ran a normal course. There was a sudden rise of temperature following a normal period of about twelve hours, the patient complained of severe abdominal pains located in the right lower segment, McBurney's point was sensitive, vomiting was distressing. The patient was kept on a fluid diet, opium given, and an ice bag applied to the abdomen. The case recovered. On the fourth day of the appendicitis a diffuse erythema appeared over the abdomen, thighs, arms, and back. Dr. Forchheimer explained the fact that an appendicitis appeared three days after the tonsillæ involvement, by considering the appendix a *locus minoris resistentiæ*, as this was a rudimentary organ, both as regards structure and functional activity.

Another case operated on for appendicitis (the patient had suffered previously from sore throat) developed signs of nephritis, endocarditis, and pyelitis in rapid succession. Considering the short time that elapsed between the operation and the breaking out of the septicæmic symptoms, the infection was probably not from the appendix. Dr. Forchheimer also reported five cases of jaundice following tonsilar infection, the jaundice appearing in three to ten days; any gastrointestinal condition that might give rise to jaundice had been excluded.

Clinical Observations on the Management of Circulatory Failure in Acute Infectious Disease.—Dr. AUGUSTUS CAILLÉ of New York, in presenting this paper, said that it was not always easy to determine the cause of circulatory failure, thus making the choice of a stimulant difficult. Several cases of septic conditions were reported, in which saline infusion, enteroclysis or hypodermoclysis had been employed with favorable results. Saline infusion was followed by almost immediate reaction; hypodermoclysis gave results in five or ten minutes. The action of each was more prompt than drugs, and was said to aid the action of drugs hypodermatically administered. The salt solution should be given until the pulse was good, then stopped. Enteroclysis stimulated the kidneys and favored elimination of poisons; it should be carried out whenever increased elimination by the kidneys was desired.

In the discussion Dr. KERLEY of New York said that the colon would not absorb more fluid than was needed by the system. He inserted a small rectal tube until it could be felt in the descending colon, employing saline solutions at body temperature in septic cases. Enteroclysis was better than any other one measure in acute suppression and in post-scarlatinal nephritis.

Dr. SEIBERT made use of enteroclysis in typhoid fever, injecting one and a half pints of salt solution every six hours; no catheter was used, buttocks slightly elevated

Dr. Jacobi said the effect of enteroclysis was twofold; a new circulating medium was supplied, if needed, and at a high temperature (110–120°) the salt solution acted as a stimulant. Shock usually meant a paralysis of the splanchnic nerves, due to an engorgement of the abdominal vessels. When the splanchnic nerves were stimuated, the body was supplied with blood that was slowly circulating in the dilated abdominal vessels, as well as furnished with a requisite amount of new circulating medium.

Dr. Cotton of Chicago thought the stimulation of abdominal ganglia would be more marked if small amounts of asafœtida and turpentine were added to the salt solution.

Chronic Parenchymatous Nephritis in a Child Treated by Renal Decapsulation (Edebohls' Operation).—In presenting a second paper, Dr. Caillé reported a case of a child, five years old, in which there had been several attacks of acute nephritis. Nine months after the last acute attack a diagnosis of chronic parenchymatous nephritis was made. Renal decapsulation was performed on both kidneys, the organs being exposed by the lumbar incision, capsules split and removed, and the kidneys replaced Recovery was uneventful. Dr. Caillé said the object of the operation was to establish a new blood supply to the kidney by removing the fibrous capsule which served as a barrier between the richly-supplied fatty capsule and the kidney. Complete recovery might be expected in nephritis following an acute infectious disease, but might be delayed months. If recovery should be delayed over six months, an exploration of the kidneys was advised; should they be found enlarged, decapsulation should be resorted to.

Specimen of a Large Thymus Gland.—Dr. Caillé presented this specimen removed from an infant six weeks old. The child had become restless, refused to nurse, had a convulsion, and suddenly died.

Dr. Jacobi said that the distance between the manubrium of the sternum and the vertebral column was about two and one-fifth centimeters, and that a congestion lasting but a few seconds might press on the trachea with sufficient force to cause suffocation. A case was cited in which a diagnosis of enlarged thymus was made, the gland was promptly drawn down out of the way, and recovery took place. The size of the thyroid might be determined by percussing from below, with the body of the child inclining forward.

Effects of Tight Diapers.—Dr. A. C. Cotton of Chicago read this paper. He said that diapers should be made of cheese-cloth, loosely applied and abundantly padded with absorbent cotton, which should be destroyed as soon as soiled. Dr. Cotton then spoke of the extreme flexibility of the infant pelvis, and said that the steady, general compression of a tight diaper tended to retard the growth and development of the structure. Skiagraphs were shown to illustrate the effects of tight binders and diapers. Dr. Cotton thought that tight diapers might be responsible for a certain per cent. of the justo-minor pelves of American women, as well as for many bowed femurs.

Some baby clothes were shown to the society, the main feature of which consisted in a bag-shaped gown gathered at the neck, with an enlargement at the shoulders. A drawstring was inserted at the bottom so that the garment might be closed and exclude draughts.

Third Day—May 28.

Two Cases of Umbilical Fistulæ Due to Tuberculous Peritonitis.—Dr. George N. Acker of Washington, D. C., presented this paper

Case I.—Male child, five years old, gave a typical picture of tuberculous peritonitis. During an attack of pertussis a rupture occurred at the umbilicus, resulting in a fecal fistula. The edges of the orifice became hard, and pus which was discharged showed the presence of tubercle bacilli. At the autopsy the fistula could be traced to a cavity attached to the abdominal wall by fine adhesions.

Case II.—A colored girl, eight years old, suffering with peritoneal tuberculosis, suddenly had a rupture at the umbilicus during a paroxysm of coughing. The rupture was followed by a discharge of muco-pus; twenty-four hours later a yellow serum was observed, having a fecal odor. The autopsy revealed similar findings to the first case. Dr. Acker thought that the rupture was probably due to a congenitally weak abdominal wall.

Diphtheria, With and Without Antitoxin.—Dr. Charles G. Kerley of New York reported observations on 159 cases of diphtheria seen by him at the New York Infant Asylum. All of these cases were well fed and housed and had the advantage of having trained nurses and physicians within call; 103 cases were treated without antitoxin, of these sixty died; of the fifty-six cases which received the antitoxin treatment, three died. In suspicious cases the injection of antitoxin should not be delayed until after a culture had been taken, but employed at once. A point not generally appreciated in the use of antitoxins was when to repeat the injections. Beneficial effects should be seen in ten to twelve hours; if there was no improvement by that time the antitoxin should be repeated. If, after twelve hours, a change in the child's condition was noticed, but fresh deposits of membrane detected, more antitoxin should be administered. The only unfavorable effect of the antitoxin was the production of an urticaria in some instances, which usually disappeared in a few days. In conclusion, Dr. Kerley said that, if there was a visible membrane, antitoxin should be injected; if there was inspiratory and expiratory obstruction, even though no membrane could be seen, injection should be made. In children under one year, 2,000 units were used; in children over one year, 3,000 units were injected, the amount to be repeated as might be necessary.

Intubation in Diphtheria.—Dr. John H. McCollom of Boston made some remarks on this subject. He said that all the members of the society could remember how hopeless a condition laryngeal diphtheria was before the days of antitoxin and intubation. A brief historical sketch of the intubation tube was given, several varieties shown, and methods of introduction and extraction demonstrated. Owing to the frequency of middle ear complications, Dr. McCollom said that he had abandoned the nasal method of feeding an intubated patient and adopted the esophageal, a soft rubber tube being used, open in the end to prevent clogging, in place of the soft catheter formerly used. Intubation should be resorted to in adults as well as in children. Eliminating moribund patients, the mortality of intubated cases was estimated at 10 per cent. In private practice, especially in the country, unless the doctor was within easy call, tracheotomy might be a better operation, since an intubation tube was often coughed up. In hospital practice, or when the patient could be watched by skilled attendants, intubation should be preferred. It was attended with little shock, patients readily gave consent, and the chances of bronchopneumonia were probably not increased. The operation was not difficult in skilled hands, and in only one case in 1,200, under Dr. McCollom's care, the tube had to be retained over one year. As a rule, the tube was left in three to four days; frequently it was coughed out at the end of forty-eight hours and replacement unnecessary. In moderate stenosis, antitoxin should be given at once without waiting for a culture, often there might be severe laryngeal diphtheria without sore throat, the process having begun in the lungs or bronchi and ascended. Rigidity of the sternomastoid muscle was a warning sign that stenosis was coming sooner or later, and should be considered an indication for immediate injection of antitoxin.

The papers presented by Drs. Kerley and McCollom were discussed conjointly. Dr. Caillé, New York, thought that the results in intubation were better when sublimation of calomel was resorted to, the calomel tending to loosen the membrane. The O'Dwyer tube, covered with hard rubber, was to be preferred. Cases of retained tube were usually due to a cicatrix resulting from an injury to the larynx; the operation was not for everyone, but required experience and practice.

Dr. Jennings of Detroit said that more than 6,000 units of antitoxin in divided doses was a waste of material in any one case. The esophageal tube should be used in feeding an intubated child or the patient to be allowed to lean over with the head low and suck through a tube. The long tube was to be preferred in private practice, being less easily coughed out.

Dr. Chapin of New York said that much pneumonia might be prevented by frequent cleansing of the tube and allowing inspired air to pass through a warm moist sponge, changed every fifteen or twenty minutes. In an extreme case a child held upside down would sometimes breathe when artificial respiration had been ineffectual.

Dr Buckingham said that feeding could be satisfactorily accomplished by raising the foot of the bed, the esophageal tube being unnecessarily severe.

Dr. Cotton of Chicago said that tracheotomy instruments should be at hand when intubating a patient, as the tube was not infrequently occluded by loose membrane

Dr McCollom said that a retained tube might be due to paralysis of the vocal cords and not always due to trauma. When loose membrane had been crowded down by the introduction of the tube, it was usually coughed out when the tube was withdrawn. Swallowing the tube was an annoying accident, but not dangerous; the thread should never be cut until the tube has been felt in the larynx. In closing the discussion Dr. Kerley said that in diphtheria there was a poison to be met and it must be met with sufficient antidotes.

Tetany of the Type Called Pseudotetanus.—Dr. Irving M. Snow of Buffalo read this paper. He said that several cases of pseudotetany had been described resembling idiopathic tetany in the onset, but differing in subsequent course and termination. An illustrative case of diphtheria with persistent trismus and opisthotonus was cited. The contractions were relieved by morphine, tetanus antitoxin having had no effect. Dr. Snow referred to several other cases of so-called pseudotetany associated with diphtheria, otitis media, and intestinal worms.

In the discussion Dr. Jacobi asked why a case of mild tetanus should be given a new name, and said that morphine and chloral hydrate had cured and relieved many cases Tetany was increased with increasing immigration and was probably associated with rickets.

The Management of the Percentages of Fat in the Feeding of Difficult Cases in Infants.—In presenting this paper Dr T. S Wescott of Philadelphia, said that the present day tendency to simplicity in infant feeding failed to bring precision into play. In most cases it was the abnormal infants which the physician was called upon to feed In meeting the requirements of such infants mathematics failed. Individual cases should be studied and the largest amount of nourishment that could be digested should be secured The natural ratio of digestive power would vary much in each instance, and a proper food could only be accurately determined by working backward—that is, from the study of the stool. In chronic gastric catarrh or catarrhal inflammations of the upper intestine it was impossible to estimate the degree of damage to the mucous membrane It was a common idea in such cases to reduce the proteid percentage to prevent curds in the stool. Holt and others had said that too high a fat percentage as well as too high a proteid percentage might cause the same condition. Vomiting was said to have been caused more frequently by too much fat than by any other condition. If by reducing the proteid percentage vomiting and other disturbances continued, too much fat should be suspected. Good results occasionally obtained by the use of condensed milk in conditions of gastro-intestinal catarrh were explained by a low fat and proteid percentage. Dr. Westcott said that the danger of under-feeding should be guarded against, and recommended a more frequent use of cream and whey mixture.

Dr Chapin said that cream was very inconstant and unless centrifuged was very uncertain. The modern tendency was to become too theoretical, figuring should be based upon a stool analysis.

Dr. Holt said that if milk was cooled at once in a quart bottle practically all the cream rose to the upper fourth in four hours. Many children did not get along well because of high fat and low proteid percentages. A healthy child could take a high fat percentage, but an unhealthy child could not stand it. It was a mistake to try to overcome constipation by increasing the fats, a condition probably dependent upon the low total solids. As long as the bowels moved every day with comfort, they should be considered normal irrespective of the amount and condition of the stools. If fats were run up because stools were thought abnormal, there was trouble. The physician should study what a child could do and not what he ought to do.

Dr. Freeman of New York advised ordering a definite percentage of cream from a reputable laboratory.

Recent Investigations Upon the Proteids of Milk.—Dr. Henry D. Chapin of New York showed several charts to the society representing analysis of 200,000 quarts of cow's milk. The percentage of albumoses and peptones were compared with the percentage of similar bodies in human milk. The proiteid percentage in milk of many animals was shown, being highest in those animals growing most rapidly. The principal object of infant feeding was to increase body cells. Proteids did not contain phosphorous, body cells did, from this it was thought that albumoses and peptones were transition forms. The question of mixing the different kinds of proteids was worthy of study.

Local Variations in the Mortality of Summer Diarrhœa.—In presenting a second paper Dr. Chapin said that while a high mortality from this affection might be largely due to great numbers of bacteria in milk there were other factors at work. Roughly speaking, one-half of the population of New York State lived in a maritime district—the other half in the country. Statistics showed that when a large number of deaths occurred in the country district a comparatively small number of deaths were reported in the maritime district and vice versa. Tables of deaths during the last ten years in the maritime and country districts together with the weather conditions were shown. In addition to the bacteria associated with the souring of milk, a putrefactive type was described, the spores of which were readily carried in dust and might thus easily infect exposed milk. It was significant that the death rate had decreased with cleaner streets. Since New York streets had been torn up in the construction of the subway the death rate from summer diarrhœa had increased 58 per cent. The heaviest mortality did not occur in the hottest months and was apparently but little influenced by humidity. Dr. Chapin said that he drew no conclusions in presenting this paper, but simply wished to call attention to a few observations.

Dr. Seibert, New York, said that the reason more children died in July than in August was because in August they were not there to get sick. Weather statistics were valueless, the terms "mean temperature" and "mean humidity" were unscientific. It was asked if six inches of rain fell in two days of a certain month and no rain fell during the remainder of the month, should such a month be called a wet or a dry month. Most of the infections of milk probably came from cow manure being shaken into pails in the process of milking and not from city dust

A Case of Auto-intoxication with Unusual Urinary

Findings.—Dr. C. G. Jennings of Detroit reported this case. A female child, ten years old, with a gouty father and neurotic mother, was subject to attacks of auto-intoxication. She became languid, tongue coated, indigestion was troublesome, vomiting became frequent. The patient relapsed into a state of coma and was especially sensitive to light and sound. On the fifth day of the trouble the extremities became cold and the pulse feeble, after a free evacuation of the bowels there was marked improvement, the patient being able to sit up two weeks after the onset. Dr. Jennings said that he wished to call particular attention to the finding of neutral magnesium phosphate in the urine, which was a rare occurrence.

Dr. Edsall said the urine should be tested for acetone and diacetic acid in such cases, for acid intoxications sometimes accompanied similar conditions.

Dr. Christopher said that he had noticed high urine acidity in cases of auto-intoxication and had known cases of cyclic vomiting to have been relieved by large doses of alkali. A child would sometimes tolerate two ounces of bicarbonate of soda a day when everything else was vomited.

Notes on the Temperature Cure in Acute Croupous Pneumonia.—Dr. Jennings read the histories of five cases of croupous pneumonia. The essential feature of the temperature cures of these cases was a sharp remission occurring on the third day. The remission, which might take place in any part of the twenty-four hours of the third day, was not accompanied by a corresponding decrease in the pulse or respiratory rate. This remission was liable to lead to errors in diagnosis.

Report of a Case of Pneumonia.—Dr. Walter L. Carr of New York read this paper. A female child eight months old, bottle fed and weighed seven and one half pounds. A paternal grandfather had died of a streptococcus infection three days after a cut in the tongue while sealing an envelope. A maternal aunt had also died of a streptococcus invasion. The child gave evidence of a rapidly extending pneumonia which was most violent in its onset. The temperature was very irregular and bore no definite ratio to pulse or respirations. Quinine was given without any improvement, a blood examination was negative. After death the pneumonia process was proven to be due to a streptococcus infection.

Officers of the Society.—The following officers were elected for the ensuing year: *President*, J. P. Crozer Griffith, Philadelphia; *First Vice-President*, Henry D. Chapin, New York; *Second Vice-President*, F. S. Churchill, Chicago; *Secretary*, Samuel S. Adams, Washingon, D. C.; *Treasurer*, J. Park West, Bellaire, Ohio; *Recorder and Editor*, Walter Lester Carr, New York. *Councillors*, F. E. Packard, *Chairman;* William Osler, C. P. Putnam, F. Forchheimer, J. C. Wilson, F. M. Crandall, T. M. Rotch.

A Case of Traumatic Tetanus Treated with Beechwood Creosote Hypodermically.—George Higginson, having failed to affect a case of tetanus with the usual remedies, determined to use creosote in large doses. Twenty minims of beechwood creosote were administered in a drachm of olive oil, hypodermically, morning and evening. Chloral and morphine were still used, and in a short time distinct benefit was noticed. The patient would entirely relax for short intervals, relieving the dysphagia, and could take nourishment. After twenty days the dose of creosote was diminished. Convalescence was slow, but in three months the patient was entirely well, and had regained his flesh and strength. The creosote in the above mentioned doses did not cause any untoward symptoms, and at no time during its administration was the urine rendered dark and smoky. The antitetanic serum seemed to have no effect whatever, the symptoms progressing rapidly during its administration.—*Nashville Journal of Medicine and Surgery.*

Book Reviews.

The Röntgen Rays in Medical Work. By David Walsh, M.D., Edinburgh. Part I. Apparatus and Methods. Rewritten by Lewis Jones, M.D., Cantab., F.R.C.P. Part II.—Medical and Surgical. New York: William Wood & Company, 1902.

No department of medical advance is attracting more attention to-day than that of diagnosis by the aid of Röntgen's discovery and the treatment of disease by various forms of light. While radiotherapy is still in its early infancy, it is growing rapidly, and the time is already near at hand when much of a definite nature may be said concerning it.

When this edition appeared there was still so little known about the therapeutic action of x-rays that this portion of the work is comparatively brief and inadequate, but six pages being given to the treatment of rodent ulcer, cancer, skin diseases, focus-tube dermatitis, etc. The bulk of the work is divided into part first, which treats of electrical apparatus and methods; and part second, giving medical and surgical applications of the ray. These are both full and up-to-date, describing the methods of producing the rays and applying them in the best way to the detection of foreign bodies, fractures, deformities, stones in various organs, and some disease-processes.

The various subjects have been ranged and treated of systematically, and alongside of the actual achievements have been placed the possible limitations and difficulties.

The whole of part first has been rewritten by Dr. Jones, and in an appendix is given the more recent advances and improvements. Taken as a whole, it must be regarded as a valuable addition to the literature of a still new but most interesting subject.

Grundriss der Pathologischen Anatomie. By Prof. Dr. Langerhaus, Prosector am Städtischen Krankenhaus Moabit, in Berlin. Third enlarged edition, with 231 illustrations. Berlin: S. Karger, 1902.

As stated in the preface, this third edition has required very little change, except in the index, which has been made more complete. The text, in part, is more condensed than in the preceding edition, whereas additions have been made to other subjects. The chapter devoted to Congenital Anomalies and Monstrosities is complete and well classified, and introduces a subject which is too often omitted in works upon general pathology. The subject of Infectious Diseases is treated as a sub-heading under the chapter of Poisonings (Vergiftungen)—that is, poisoning occurring from infection by vegetable organisms as opposed to animal organisms; this latter class occupying a parallel sub-heading and including diseases caused by worms, insects, infusoriæ amœbæ, etc. Although it cannot be said that the reader of German medical literature is limited in his selection of a work upon general pathology, this volume will be found to cover the subject matter thoroughly, is concise in statement and accurate in diction.

The Study of the Pulse, Arterial, Venous and Hepatic, and of the Movements of the Heart. By James Mackenzie, M.D. (Edin.), Burnley. 325 pages. New York: The Macmillan Company. Edinburgh and London: Young J. Pentland, 1902.

This treatise differs greatly from the usual publications which are devoted to the study of the pulse. In it we find reproduced numberless graphic tracings, often with synchronous records of two or more pulsations taken at the apex, the radial, the carotid or over the jugulars and the liver. These are given as facts, from which the reader can deduce his own conclusions or assent to the explanations of the author. The author has endeavored to make less obscure the many unexplained phenomena noticed in circulatory disturbances, and in so doing has rendered a distinct service to both the physiologist and the clinician.

The work certainly proves the value of sphygneographic tracings when under the supervision of one familiar with its use. Especially is this true of the simultaneous tracings, for by no other means can we judge what the different portions of the circulation, ventricular, auricular, arterial, and venous, are doing at certain times. The significance of pulse irregularities, arterial tension, venous and hepatic pulsation, all of such speculative interest, are discussed with fairness and explained to a great extent. The volume contains much that is new, and is splendidly enriched with the author's tracings, numbering over 300.

The International Medical Annual. A Year Book of Treatment and Practitioner's Index. New York: E. B. Treat & Co., 241-243 West 23d St. Chicago: 199 Clark St.

The twentieth year of the "Annual" has been attained with credit. Yearly it has grown in worth as well as in size until it now covers almost every branch of medical and surgical progress. No year book can be complete and above criticism, but this one has successfully aimed, it would seem, to give the greatest number of readers the greatest amount of practical information in the least space. May it have another twenty years of usefulness.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare M.D., assisted by H. R. M. Landis, M.D. Philadelphia and New York: Lea Brothers & Co., 1902.

In the March number of this serial, the list of contributors includes the well-known names of Crandall, Frazier, Hektoen, Packard, Randolph and Thomson.

The topics are Surgery of the Head, Neck and Chest; Infectious Diseases, Diseases of Children, Pathology, Laryngology, Rhinology and Otology.

Recent advances in all these departments have been carefully gone over and little of essential importance or interest has been omitted. The work is put out in excellent style, and when completed for the year makes a good reference library-set.

International Clinics. A Quarterly of Clinical Lectures and Especially Prepared Articles on Medicine, Neurology, Surgery, Therapeutics, Obstetrics, Pediatrics, Pathology, Dermatology, Diseases of the Eye, Ear, Nose, and Throat, and Other Topics of Interest to Students and Practitioners. By Leading Members of the Medical Profession throughout the World. Edited by Henry W. Cattell, A.M., M.D., Philadelphia, with the collaboration of John B. Murphy, M.D., of Chicago; Alex. D. Blackader, M.D., of Montreal; H. C. Wood, M.D., of Philadelphia; T. M. Rotch, M.D., of Boston; E. Landott, M.D., of Paris; Thomas C. Morton, M.D., Chas. H. Reed, M.D., of Philadelphia; J. W. Balantyne, M.D., of Edinburgh, and John Harold, M.D., of London. Volume IV. Eleventh Series, 1902.

The high scientific tone of the "Clinics" is well maintained. Jacobi, Wood, Burnett, Brocq, and others contribute to the Section on Therapy. The names of Duckworth, Bruce, Curtin, Walsh, and others equally prominent are found under "Medicine:" Walton, Krauss, and Pick treat of Neurology. In Surgery, Senn, Cantlie, and Deaver are among the contributors.

The volume contains nearly 300 pages and is well illustrated.

Traitement des Maladies Contagieuses de l'Appareil Générateur (Guide Pratique). Par Dr. F. Buret. Paris: Sociéte d'Éditions Scientifiques 4, Rue Antoine Dubois, 4, 1902.

In this volume of two hundred odd pages Dr. Buret gives directions for treatment by large injections of insoluble salts of mercury; for making accurate scientific observations on syphilitic reinfection, and discusses with much detail the operative procedures connected with the hypodermic method. He asks all who have knowledge of reinfection after cure to communicate the case for future publication.

Rough Notes on Remedies. By Wm. Murray, M.D., F.R.C.P., London, Newcastle on Tyne. Fourth Edition. London: H. K. Lewis, Philadelphia. P. Blakiston's Son & Co, 1012 Walnut Street, 1901.

The degree of popular favor accorded Dr. Murray's "rough notes" is indicated by the appearance of this fourth edition. The preface contains a letter from Canada telling of a life saved by one of the suggestions. In this edition the author adds a chapter on "Roxbury as a Health Resort."

The Operations of Surgery. Intended especially for those recently appointed on a hospital staff and for those preparing for the higher examinations. By W. H. A. Jacobson, M.Ch., Oxon., F.R.C.S., Surgeon to Guy's Hospital, and F. J. Steward, M.S. London, F.R.C.S., Assistant Surgeon to Guy's Hospital, etc. Fourth edition. 550 illustrations. Vol I. and Vol. II. Philadelphia: P. Blakiston's Son & Co., 1012 Walnut St., 1902.

When this work appeared some years ago in a single volume, it at once became popular with students and recent graduates, on account of its obvious merits, and subsequent editions have served only to fix its popularity more firmly. It now appears in two large volumes, and its original author has called to his assistance men who are well qualified to assume the task of bringing it up to modern requirements. The operations of surgery are arranged according to regions, and Vol. I covers the surgery of the hand, arm, head, neck, face and thorax, with all operations upon any given part under one heading, a method which has some advantages over that which arranges matters according to the kind of operation. Much of the matter does not differ materially from that in previous editions, but some of the more recent surgical advances receive full attention. We might mention the Hartley-Krause operation for trigeminal neuralgia, and the operation for removal of the cervical sympathetic in exophthalmic goiter, but the newest experiences in ligature of the innominate artery are not mentioned, perhaps, because they are too recent. All operations are minutely described, and enough statistical information is given to enable the student to judge of the relative value and dangers of the various procedures. Vol. II. contains chapters on the surgery of the abdomen, hernia, the kidneys and ureters, the female pelvic organs, the whole of the lower extremity and the vertebræ column. Much of the text is the same as in the last edition, but the chapter on the radical cure of hernia is considerably improved. The recent advances and novel manœuvres in the surgery of the ureters receive considerable attention, but we think the chapter on appendicitis could be improved upon in regard to completeness. The latest operations upon the carcinomatous breast are fully described.

The two volumes undoubtedly form one of the most satisfactory works on operative surgery extant, but we should like to see some of the old illustrations suppressed and new ones introduced more in conformity with what actually occurs at surgical operations. Many of the engravings have been in use for years and are antiquated.

The Social Evil. With Special Reference to Conditions in the City of New York. A Report Prepared under the Direction of the Committee of Fifteen. New York and London: G. P. Putnam's Sons.

This may be considered rather as an essay upon the various problems associated with prostitution in general than as a report of a committee appointed to inquire into the causes of a supposed increase in gambling and the social evil in this city. The conclusions and recommendations of the committee are included in twenty pages at the end of the book, and the "Cadet" system and tenement-house evils are dwelt upon. The work is published in an attractive manner and there is much contained in it of value to all having these questions at heart or brought before them in one way or another.

The Diagnosis of Surgical Diseases. By Dr. E. Albert, late Director and Professor of the First Surgical Clinic at the University of Vienna. Authorized translation from the Eighth Edition by Robert T. Frank, A.M., M.D., with 53 illustrations. New York: D. Appleton & Co., 1902.

Albert's work upon the diagnosis of surgical diseases has long been a popular book with German readers, and now those unfamiliar with its original language have it presented to them in its present form. The work is strictly one upon diagnosis, and is compiled in the form of a series of lectures, arranged systematically according to anatomical regions, beginning with the head and proceeding to the trunk and extremities. The clinics of Vienna have supplied Albert with an enormous amount of material, which fact has made his generalizations most sound. His style is clear and holds the interest. Surgically speaking, this book lacks completeness and fails somewhat on the score of accuracy, but this fault is apparently unavoidable when lectures are the chief source of literary material. In its present form the American student will no doubt find this a useful volume to amplify his course of didactic lectures and as a source of systematized information. The translator's work has been satisfactorily accomplished.

The Medical News Pocket Formulary for 1902. By G. Quin Thornton, M.D., Demonstrator of Therapeutics, Pharmacy and Materia Medica in the Jefferson Medical College, Philadelphia. Fourth Edition, Revised. Philadelphia and New York: Lea Bros. & Co., 1902.

There are many new formulæ in this edition, and while the newer remedies have received notice, the older combinations of drugs which have proven of value in particular conditions of ill health have not been neglected. As no credit is given, the prescriptions are all supposed to be devised by the author himself.

Psychical Vertigo.—N. Vaschide and Cl. Verpas treat of the sensation of disturbance and timidity felt by certain persons when looking down from a great height, a sensation which leads them to fear that they will be induced to throw themselves over, and which makes them imagine that they are doing it. This passes under the name of vertigo, but, as a rule, there is no giddiness, nor are there any visual troubles. The sensation is a purely psychic one, and, from its symptoms, as described by the, patients, by the general characteristics of these patients, by its mechanism, origin, and psychological structure, is a true obsession. Psychical vertigo is a descriptive title for the affection.—*Revue de Médecine.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending June 21, 1902:

	Cases.	Deaths.
Measles	217	18
Diphtheria and croup	340	43
Scarlet fever	226	18
Smallpox	26	11
Varicella	19	..
Tuberculosis	234	135
Typhoid fever	33	11
Cerebro-spinal meningitis	..	3

Imperial Medico-Military Academy of St. Petersburg.—Marcou describes this medical school of St. Petersburg for physicians of the army and navy. This is the only school of the kind in Russia, as the University of St. Petersburg has no medical department, this school taking the place of it. It is an ancient institution, having celebrated its centennial in 1898. It is the oldest medical school in Russia, and its history is connected with the first rational efforts at instruction in the empire. Peter the Great was the first to found a school of medicine. He built several hospitals, but there were no physicians to manage them. In 1708 the Emperor Paul signed a decree ordering the construction of the Medico-Surgical Academy. Gradually it rose to its present position. The German influence in the field of medicine has been very strong, but even at the time when French culture dominated all the departments of intellectual activity in Russia, its influence in medicine was *nil.* In the olden times it was the seminaries of priests, especially, which furnished the medical students, for the medical career could scarcely be called brilliant. But, gradually, the situation has been improving, and a larger number of young men have turned their attention to medicine. Even now the Russian military physician is more poorly paid than any other officer of corresponding grade. Only the Russian Christians or Mahometans are admitted to the school; Israelites are refused. The number of students is limited to about 750. That is a small number for a large capital. But there is also the Institute for Women Physicians, with 1,200 students. The cost of the course for a year is sixty roubles, or $32. The course extends over a period of five years, and, after finishing it, the student is at liberty to practise anywhere in the vast empire The students enter the school at about eighteen years of age. They wear a uniform, and carry a saber, and are officially under military discipline. The students and professors, in reality, form part of the army. For each course there is a commanding colonel. He inspects the students, signs their passports and all sorts of papers, and, in case of any disturbance, he judges the culprits. But, in spite of appearances, no trace of military spirit exists in the school. In general, the students appear to be very quiet, and hard workers. At the end of five years there is a comprehensive and long examination, consisting of twenty-eight parts, which alone gives the right to practise. About 150 students are given the title of physician, with "satisfactory" or "extremely satisfactory." From this number about seventy can be presented as candidates for the Institution of Improvement. A thesis, usually on general pathology, is presented by each candidate, without any signature. These theses are compared, and the ten most desirable are designated, and the authors are "Physicians of the Institution of Improvement." These young physicians are connected with the school for three years. The first seven are paid $53 a month. The other three are not paid, but have the same privileges. They choose a specialty, and study with a professor for the three years. They pass examinations during this time to obtain the title of Doctor of Medicine, which is of more value than the first title of Physician which they have received. Every year several of the young physicians are sent to a foreign country to study in the line of the specialty which they have chosen. After a period of two years of foreign study, the student is eligible to the examination leading to the title of Privat-Docent. Thus the student will have spent, at the end of this time, ten years in study -five in the academy, three with a Russian professor, and two abroad. The professor is at liberty to choose his own assistant. As to the election of professors, when a chair is vacant, the fact is published, and every physician in Russia is at liberty to present himself as a candidate. Generally, they are chosen from the old assistants, or from the provincial professors. The professor is calm in his manners, and speaks without gesticulating. The scholastic year lasts from the 16th of September to the 1st of May. The first two years are devoted to the preparatory course. The last three years to the special medical courses. The theoretical work lasts from nine o'clock in the morning to two o'clock in the afternoon. Laboratory work is very comprehensive and carried out on a large scale. To this the afternoon and evening hours, especially, are given up. The Minister of War is very generous, and large sums are devoted to the maintenance of the laboratories The instruction in the hospitals amounts to very little, and a vast amount of material is wasted. At the end of the first year, if the examinations are not satisfactory, the student is dismissed from the school. The examinations of the other years are less severe. This medical school at St. Petersburg supports a complete corps of medical instructors, which compares favorably with the faculties of the large capitals of the West. The writer believes that the theoretical instruction and the laboratory advantages are more comprehensive than the same work in Paris. On the other hand, the hospital work in Paris is superior, for the students can work in all the hospitals of the city. Finally, everything is ruled methodically here, and the student is not left to himself as he is in Paris.—*Archives Générales de Médecine.*

An Ambulatory Treatment of Leg Ulcers.—Guadin describes a method of treating leg ulcers which allows the patient to keep at work. His cases have all been varicose ulcers, but he sees no reason why other kinds may not be treated in the same manner with equally happy results. The leg is just washed with water and soap, and then, with the exception of the ulcer, is entirely covered with a paste made of iodocresol, gelatin, glycerin, and water. This mixture is melted in a water bath and spread on thick with a brush. The ulcer is powdered with traumatol in powder. Traumatol is a combination of iodine and cresylic acid; it is an antiseptic as powerful as iodoform but without the disagreeable odor; neither does it irritate the skin. After powdering the ulcer, it is covered with gauze impregnated with traumatol, over which a layer of absorbent cotton is placed. Before the paste on the leg is dry, there is applied to the leg a starched bandage, first softened with hot water. This is applied to the point of the leg opposite the ulcer, and the ends are crossed from the two sides of the ulcer, so as to draw together the edges of the ulcer and diminish its extent. This manœuver is continued throughout the application of the bandage and ensures a certain compression. Then a bandage is put on from the toe to the hip. The first dressing should remain in place two or three days, according to the amount of secretion produced—secretion which the traumatol disinfects and deodorizes. The subsequent dressings remain longer. The writer has left one in place more than fifteen days. In order to remove it, the leg is plunged into warm water till the bandage is softened. By this dressing the pains immediately lessen, the bad odor disappears, and a cure is established in three or four weeks, and the patient can continue at his work.—*Le Caducée,* May 3, 1902.

Recent Advances in the Study of Immunity.—W. Silberschmidt reviews the recent advances which have been made in the study of immunity, and cites the views of Ehrlich, Morgenroth, Gruber, Buchner, Bordet, Baumgarten, and Metchnikoff with respect thereto. Although much that is of importance along this line has been ascertained, nevertheless the treatment of infectious diseases has not as yet been materially advanced thereby. In immunization the amboceptors play the chief rôle nevertheless a sufficient amount of alexin is necessary. It has been shown that in the blood of persons suffering from bacterial diseases the alexin is greatly reduced in amount. For this reason Wassermann has recommended the inoculation of normal serum rich in alexin as a means in the treatment of infectious diseases. This has been tried in typhoid fever, but not as yet sufficiently to warrant definite conclusions. Metchnikoff has endeavored to produce an acquired immunity by the inoculation of a specific leucotoxic serum, thus producing a hyperleucocytosis. The result of this method is also still in doubt. Morro has shown that the serum of breast-fed children contains more alexin than that of those who are artificially nourished. In this manner the greater resistence of breast-fed children is to be explained. The recently gained knowledge with respect to precipitins, agglutinins, hæmolysins, etc., has opened a new field in bio-chemistry and possesses great forensic value. It is certain that the differentiation of human from animal bloods is greatly simplified thereby. Human blood which has been dried for five, eighteen or twenty-five years may thus be easily identified.—*Correspondenz-Blatt für Schweizer Aerzte.*

Toxæmia from Suppuration in the Temporal Bone.—H. Eulenstein states that suppurative disease in the temporal bone may cause general infection in two ways. The inflamed wall of the sinus may permit the passage of the bacteria or their toxins into the blood, so that death may occur from toxæmia without any special increase in the inflammatory process, or the bacteria may be taken directly into the circulation by the large, and especially the small, vessels, and thus be permitted to increase with great rapidity in all parts of the body. We do not yet know why the same kind of microorganism behaves with different degrees of virulence under different circumstances though individual susceptibility must play some part. Powerful stimulation and saline infusion are important parts of the treatment, but the value of the antitoxic serums is not yet settled. In all cases it is important to remove the focus of infection as soon as possible.—*Archives of Otology.*

The Treatment of Wounds.—E. D. Martin thus sums up the treatment of wounds: (1) Cleanse the hands by washing with soap (that manufactured by process of boiling is the only soap free from germs), and scrubbing with brush for ten minutes; then cleanse the subungual spaces, scrub again for five minutes, wash or scrub in alcohol one minute, wash in permanganate and oxalic-acid solution, or solution of chlorine, for five minutes. These solutions are not necessary for the ordinary handling of wounds, and can be substituted by alcohol and bichloride 1-1000, and afterward rinsing in sterilized water; (2) Prepare the skin by scrubbing with soap and brush five minutes or more, cleanse with alcohol, and wash off with bichloride 1-1000. Cleanse the wound with peroxide and antseptic solutions; dress according to the character of the wound. (3) Instruments are best prepared by scrubbing with soap and water and sterilizing in a 1 per cent. solution of cooking soda for at least five minutes; (4) Towels, dressing, etc., are prepared by sterilizing for at least twenty or thirty minutes. Moist heat (steam) is best, as it is more penetrating.—*New Orleans Medical Journal*

The Treatment of Hæmatemesis.—H. Hervieux enjoins both moral and physical rest in a case of hæmatemesis If syncope is threatened, rhythmical tractions of the tongue according to Laborde's method, are of value, conjoined with injections of caffeine or of ether. Dry cups should be applied to the chest and the abdomen, or ice bladders over the epigastric region. The ingestion of cracked ice seems to be of use in slow or slight hæmatemesis. Some authorities recommend the injection of morphine. The following potion given in tablespoonful doses every two hours has a beneficial effect: Bonjean's ergotine, 1 dr.; Gallic acid, 9 gr.; Extract Thebaic, 2 gr.; Syr. of Terebenthine, 1 oz.; Lime water, 4 oz. The administration of this potion should be continued until all hemorrhage has ceased. After the attack the patient will usually be weak and anæmic. Tonics should be given and all hygienic measures taken to restore health and strength.—*L'Union Médicale du Canada*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended July 5, 1902:

MOSQUITO WORK IN HAVANA.*

By W. C. GORGAS, M.D.,

MAJOR AND SURGEON, U. S. ARMY.

I TAKE it for granted that the work of Lavaran and Ross has been generally accepted by almost all medical men as proving that the Anopheles mosquito is the only means of transmitting malaria, and that the work of Finlay and Reed has proved still more conclusively that the Stegomyia mosquito is the only agent in the transmission of yellow fever.

At the beginning of 1901 the whole attention of the Sanitary Department of Havana was centered upon ridding the city of yellow fever, and our measures were taken exclusively for this purpose. The results upon malaria have necessarily followed from the mosquito work.

Our scheme at the beginning of 1901, so far as mosquitos were concerned, was, in the first place, to destroy all the Stegomyia mosquitos we possibly could, so as to leave as few as possible to transmit the yellow fever from patient to patient. In the next place, to prevent as much as possible those that escaped from biting yellow-fever patients, and thus transmitting the disease. And in the third place, when mosquitos had escaped our first two lines of defense, to have a third line and endeavor to kill all that had become infected.

With the idea of destroying all the mosquitos possible, we formed a brigade, naming it the Stegomyia brigade, which worked within the houses. The Stegomyia mosquito breeds principally in the yards of the more thickly settled portions of the city, in all fresh-water collections, such as rain-water barrels. The water supply of Havana is very hard, and nearly every house in the city has a barrel of rain water for domestic purposes.

Early in the season the Mayor issued an ordinance requiring every collection of water in the city to be kept mosquito proof. After one or two inspections this was enforced by fines. Wherever a collection of water was found not protected as required, the owner was fined.

The Stegomyia brigade is divided into seven sections; each section has a portion of the city assigned to it. The section consists of an inspector and two laborers, who accompany him in his inspections. Every house in his district is visited by this inspector. The inspectors report upon the condition of the water collections as to larvæ, and the manner of their protection. On this report the department acts as to fining the tenant or owner, according as the responsibility rests.

The oilers pour crude kerosene oil into all the drains, privies, cess-pools, etc., that cannot be otherwise protected. If the families are poor, the department covers their water barrel and puts a spigot in the bottom. Havana has no general sewerage system, but each house has a cess-pool. Sometimes a cess-pool will have an outlet into some neighboring drain, or it may not have any outlet at all. All these cess-pools and the drains leading thereto are favorite breeding-places for the common Culex pungens, and to a very slight extent for the Stegomyia. The only way of managing these is by oiling. Practical experience has taught us that when mosquitos are troublesome in a house, they are almost invariably bred in that house, or in the contiguous houses, and of the Stegomyia that can be stated as a fact almost without exception. It is a very domestic mosquito, seldom leaving the immediate neighborhood of the place of its birth. The work within the thickly inhabited part of the city has had a most striking result in the general decrease of the mosquitos. The chief of the division estimates that we have not more than one-tenth the number of mosquitos in the city at present that we had at this time last year, and so far as I can observe, I can concur in this estimate.

We can give accurate figures as to the number of houses which had deposits of larvæ. When the work was first commenced, the ground was carefully gone gone over by inspectors and a report made that mosquito larvæ were found on 26,000 different premises. At the last inspection, going over the same ground, less than 200 premises contained larvæ. In this work during the past year we have employed constantly from thirty to fifty men.

Havana has its population crowded into a very small area, the garden and farm districts coming right up to the city proper. This was due to the fact that the Spanish military authorities drew a line beyond which they would not allow buildings, so that the gardens commence at these buildings. These gardens are constantly irrigated, irrigation ditches traversing the country in every direction, and they are great places for breeding mosquitos, particularly the Anopheles.

For work in this district we organized an Anopheles brigade; at one time during the summer, we had as high as 150 men at work; at another time during the past winter we reduced it to forty men. The brigade was entirely separate from the Stegomyia brigade, was under charge of a chief, and was divided into as many sections as were necessary for the work in hand. They cleaned all the irrigation ditches and the small streams, of grass, waterlilies, and obstructions, and ditched the land, and stopped irrigation on any extensive scale. The irrigation in the gardens was not found so objectionable, as the water did not stay on the ground, but was merely collected in holes and put on the ground by hand. But in the grass lands which made up the greater area around the city, we were obliged to stop irrigation altogether. These irrigated grass lands were found to be great places for the breeding of Anopheles, particularly such lands as were used for grazing purposes; the cattle making a hole wherever they stepped in the muddy ground, which retained the water and made an ideal receptacle for breeding Anopheles. In certain cases when we could not get at the water collections in other ways, we used oil. But we have about given up oil in the outlying districts. It is very much better to drain. Oil on a large area of water will blow to one side and is very difficult to distribute.

We have extensive swamps about a mile from the city, across the bay, covering several square miles.

---

*Read before the Sanitary Conference, Charleston, S.C.

These we have not attempted to drain in any way, as we have no evidence of mosquitos having come from them.

This is a rough description of the work we have inaugurated for preventing the breeding of mosquitos.

To prevent the mosquito from becoming infected from the yellow-fever patient, we have screened, at public expense, every yellow-fever case as it has occurred, having the family designate the room or rooms they want to occupy, and at once putting up wire screens at the doors and windows, and stationing a guard at the door to see that proper precautions are observed with regard to keeping the door closed.

With the object of destroying the infected Stegomyia, we organized three fumigating brigades of thirteen men each, under the direction of a chief. These at once went to the houses, and as soon as the patients were screened, went to work killing mosquitos. The screening was generally completed within two hours after the case was reported. Each room in the house outside of those occupied by the patient was closed; the cracks were carefully pasted, and pyrethum powder was burned at the rate of one pound to every 1,000 cubic feet of air space. At the end of three hours the room was opened, and the mosquitos were swept up and destroyed. The whole house was gone over in this way, and on the possibility of some of the mosquitos having escaped, the houses adjoining the infected house were treated in the same way. On an average, 150 pounds of pyrethrum were used to a disinfection.

As soon as the patient had recovered or died, the rooms occupied by him were gone over in the same way, and the infected mosquitos were killed before the screens were taken down.

Pyrethrum is not the best insecticide, but it was used because it was least objectionable to the people being fumigated. Sulphur is very much better, but it injures so many fabrics that we never use it in rooms where any injury can be done. From the stupor caused by the pyrethrum powder a certain number of mosquitos will revive when exposed to the fresh air, and for this reason, after the fumigation the mosquitos have to be carefully collected and destroyed in some other way.

The habits of the Stegomyia have greatly assisted us; they seem, as a genral rule, not to leave the neighborhood of their birth-place, and for this reason we were able last summer to get all the infected mosquitos around each focus as it developed by killing the mosquitos in the way described.

In this work we have employed through the year an average of about forty men, and spent about $7,000. The results are, first, the extermination of yellow fever; second, a marked decrease in malaria.

Yellow fever is known to have been present in Havana ever since the English occupation of 1762, not a year having passed since that time without many deaths from this disease. I insert here a table of deaths from yellow fever covering the period since 1889. The records of Havana, as far back as they go, show the same condition of affairs as to this disease.

From this table it will be seen that, for the year of mosquito work, from April 1, 1901, to March 30, 1902, there were only five deaths from yellow fever in Havana. Since September 28, 1901, there has not been a single case. The maximum for the same period, according to the table, is 1,385 in 1896–97; the minimum, 122, in 1899–1900; average, 467. These results, it seems to me, are due entirely to the mosquito work.

Our reports for 1900 show 344 deaths from malaria; for 1901, 151 deaths; for the first four months of the present year, twenty-six deaths.

The decrease in the death rate from yellow fever and malaria is directly attributable, I think, to the mosquito work. Havana is the first place in which mosquito work has been attempted in a systematic way and on any large scale, and we can accurately measure its results, as we have done above, by taking the number of deaths before the mosquito work and after. This work, as above described, has been going on in Havana for the past fourteen months. In the prevention of yellow fever it has attained entire success, and while we cannot hope for such effective results as far as malaria is concerned, the statistics show that without doubt the work has decreased malaria to a very great extent.

How far such a plan as ours could apply to country districts and small towns, would have to be determined by experience; but I am inclined to believe that the same general outline would apply everywhere. Mosquitos generally do not travel very far; those that annoy houses come from the immediate neighborhood, and I believe that, by destroying the breeding places in a town, or immediately around the houses, the diseases conveyed by mosquitos can be very greatly decreased.

APPENDICITIS AS VIEWED IN THE EARLY PART OF THE LAST CENTURY, WITH A FEW NOTES ON THE ESSAY OF MÉLIER.

By THOMAS H. MANLEY, Ph.D., M.D.,
NEW YORK

At the annual meeting of the American Medical Association held in Atlantic City, N. J., in 1900 it was my privilege to present a contribution on "Appendicitis in Children." This was published in the *Journal of the American Medical Association*, May 12, 1901. In that essay I stated that the first published description of the pathology of appendicitis, was by "Mélier."

In making this statement I was aware that it was not supported by any acquaintance with the original publication, but it was borrowed from a monograph, by a very painstaking reliable author.

Last August a noted English author sent to me a note in which he challenged the accuracy of my citation, asserting that the first to write on the pathology of the appendix was a London physician in 1838. He informed me that he had then in preparation a work on "Disease of the Abdomen" and was anxious to secure reliable data, and concluded by demanding the date of Mélier's publication, the journal it was published in, and where?

It was now evident that the veracity of my statement was questioned, and in order to support it, the original was indispensable. After an extended correspondence with the principal medical libraries in America, and an examination of the vast bibliographical store of the New York Academy of Medicine, I was about to give up further effort, when Mr. E. B. Browne, the courteous librarian of the New York Academy of Medicine, suggested an appeal to the library of the Surgeon-General of Washington, D. C. From this great library the original brochure of Mélier was generously loaned me.

On a most superficial perusal of this pamphlet, I realized that it was a veritable treasure in its way; that it contained the report not of one case only of appendicular lesion, but of nearly a dozen, and that, though published now seventy-five years, there has been essentially no advance on the pathology of the disease or a more rational conception of its treatment.

Hence, I have ventured to translate it verbatim, and add a few notes.

(Translation from the original.)

A Memoir of Some Maladies of the Cæcal Appendix. By Dr. L. Mélier.

From *Journal of Medicine, Surgery and Pharmacy*, 1827. Second series, 110, 39, p. 317. (From a reprint.)

M. Mélier says, anatomico-pathological researches have nearly nothing on diseases of the cæcal-appendix. Authors appear to have given it no attention. In fact, this omission seems justified by the slight importance of this organ, this vestige, of the uses of which we are ignorant and of the purposes in the economy, we know nothing.

It is well known that physiologists have operated on the cæcal-appendix of animals, removing it after ligation, when it was found to contain fecal matter, or foreign bodies.

I shall not stop to describe the appendix nor will I hazard an opinion on its usage, as vague conjecture and hypothesis are without interest. I shall note some of its diseases, and especially the fecal accumulations in its cavity. We will record here two observations, verbatim, presented at the Academy of Medicine in 1834 by Dr. Louyer Villermay and others from various sources.

Case I.—**Acute Inflammation of the Cæcal Appendix; Gangrene of the Organ and Death on the Fourteenth Day.**—W. G., thirty-five years of a full habit, usually enjoyed good health, and led a sober life; was seized, suddenly on the 10th of November, 1823, at 5 A.M., with a severe pain *in the right side* [italics the author's] of abdomen had bilious vomiting; all *this part* of the abdomen *extremely sensitive* to the touch. Testicle on right side strongly retracted. The pulse was somewhat slow.

Patient had observed that the *dorsum of the* right foot was cold for four days prior to the invasion M. Selévestre, his ordinary physician, prescribed emollient drinks, enemata, with twenty leeches to the anus. The punctures from these bled all day. In the evening the pain was less severe and vomiting had ceased. But the pulse had quickened and the night was troubled.

On the second day thirty leeches were applied over the right iliac fossa. Nitrated milk was prescribed and emollient cataplasms applied. In the evening the pulse was hard; in spite of the diminution of the beats; twenty more fresh leeches were applied over the site of the greatest pain. Every six hours a warm bath was given; during the night green vomiting returned, great pain attending each effort.

On the morning of the sixth day the patient was without pulse, cold and extremely restless, but had no pain. Vomiting continued and the Hippocratic facies was pronounced. In order to diminish the vomiting and the great heat of which he complained, iced lemonade was prescribed and taken with relish. Meanwhile I enveloped the lower members in sinapisms. At midday he expired without agony.

Autopsy Made Twenty-four Hours after Death.—Found the right testis drawn firmly up to the external ring. The abdomen was opened. *In the right iliac fossa* was discovered about three ounces of black serous fluid, exhaling a foul gangrenous odor. In the middle of this floated the cæcal appendix; it was *about a third longer* and larger than commonly; black, involved by *gangrene* and *putrescent.* It was detached without effort. This gangrene was confined to the appendix. *The cæcum was everywhere healthy*; the omental investment of the cæcum was in patches, gangrenous and adherent. The subperitoneal tissue was infiltrated as far up as the kidney.

The mucous membrane of the stomach was reddened and thickened, but the intestine and all the other organs were healthy.

Reflections.—When one reads of the grave accidents in this case and the promptly fatal issue one would expect some spread of the disorder to the viscera, and is astonished to find the appendix the only organ diseased

It was evidently a case of inflammation of the elongated organ, with advance to gangrene, which had been the cause of all the grave accidents and death.

All the symptoms were in the right iliac fossa, the only seat of the disease. It was for these symptoms the leeches were twice applied and a bleeding from the arm was resorted to. In spite of these measures and energetic treatment, the affection of a circumscribed organ, without function, carried the patient off in three days.

The second case recorded by Dr. Louyer Villermay is not less interesting than the first.

Case II.—**Acute Inflammation of the Cæcal Appendix Terminating in Gangrene and Death on the Third Day.**—Patient, a man thirty-seven years old, endowed with a good constitution, had an inguinal hernia, well supported by a truss; on July

21, 1821, an hour after his supper, he felt a general malaise with nausea and sharp pains over the umbilicus, and he had great oppression. He vomited his supper with a very green viscous substance, but the pain and distress lasted all night. Enemata gave no relief.

Twenty-second inst., at 6 A. M., momentarily calm, but extremely feeble; face pale, tongue humid, thirst intense, pulse small, hard, and frequent, cramps in calves of legs. The umbilical region sensitive, the hypochondria full, hernia reduced. Respiration and speech painful. Sweetened flaxseed tea ordered, with fomentations over the abdomen. Patient to submit to leeching or bleeding. By two o'clock vomiting recommenced, of a dark green color, there were fecal discharges of the same color, dysuria, considerable distention of the abdomen, some pain in the *right lumbar region*, and frequent chills. During the night the patient was very calm, rather somnolen than sleeping, muttering, vomiting less, and complaining of sharp thirst at intervals.

Twenty-third inst. Integrity of the faculties, pulse small, feeble and irregular, the abdomen not painful. At 6 o'clock syncope; death soon after.

Autopsy: On opening the abdomen, a pyramidal body appeared in the right iliac fossa—the cæcal-appendix—this was about 3½ inches long and an inch thick at its base. Here a large, violet-black plague of gangrene encircled it.

The mucous membrane was very thick and of a silvery white; where it approached the cæcum it was black and disorganized. When the cæcum was opened *it was found perfectly healthy* till the mouth *of the appendix was approached*. The intestines were distended with gas with no structural changes, but the mucous membrane of the stomach showed traces of inflammation. The other organs showed nothing unusual.

Reflections: In this recorded case the affection of the cæcal appendix was as circumscribed as in the first, and had a more rapidly mortal termination, the disease remaining through only one day and night. Perhaps, in view of the great violence of the malady, sufficiently active remedies were not put into use. As in the preceding case, all the abdominal organs were healthy, even the cæcum itself; its appendix alone leading to the accidents and death.

CASE III.—**Obstructive Inflammation, Gangrene and Perforation of the Cæcal Appendix, Effusion into the Peritoneum; Death.**—M. Laent, age thirty-five, strong constitution, sanguine temperament, considerable *enbonpoint*. Always enjoyed good health, was never ill; only had effusion within knee-joint when a child, which left the knee anchylosed.

He was seized in the night of July 3, 1824, with a colic. I was called in the morning. His state was as follows: He had severe pain in the abdomen, which augmented at intervals, borborygmi, some nausea; the abdomen was supple and nowhere painful on pressure, tongue white and moist, pulse small but not frequent, general anxiety. Some days before he complained of heat of the belly, of constipation, some colicky pains, which he attributed to severe muscular effort and suppression of perspiration. After the bath the pain diminished; patient was tranquil. In the evening pain recurred and sleep was interrupted. On the 5th but little colic, no fever, but abdomen was now sensitive to pressure. Passed a fair day. In the evening, the same day, the belly was sensitive and colic more frequent; prescribed twenty leeches, with some relief following.

The following day the man passed two copious fecal movements, bilious and very fetid. This was attended with intense colic, but was followed by much relief.

Sixth day diarrhœa followed as a sort of crisis, and this was succeeded by so much relief that no more leeches were applied; the patient now had no doubt of his early recovery, and this hopeful view was shared by myself.

The painful aspect of the visage particularly seemed effaced after the large spontaneous evacuation, and I deluded myself by this sign into giving a hopeful view of the situation. Patient now had neither thrist nor fever; he received friends through the day, and fed himself; was very comfortable at 6 P.M.

Suddenly, while taking an injection, he was seized with atrocious pains in the belly; he lost consciousness, his body became cold and covered with cold sweat. I was called (I had intended to make no more visits); I soon arrived, found the belly painful on the least pressure; the man was nauseated, making frequent efforts at vomiting; he had a small pulse, and was in a miserable condition. Appreciating the great danger and wishing for additional counsel, I called Dr. Fourcadelle, who continued with me in charge. It was evident now that there was peritonitis, which had suddenly developed.

But what could be the cause of this sudden and terrible change? The abdominal passages were examined with care, but no hernia was found. We concluded that there had been a *spontaneous perforation*. Prescription, twenty leeches on the abdomen, fomentations, and a little milk. These had no effect, symptoms persisted, but they became more and more alarming, the patient soon became much weaker, prostration was setting in, which is so characteristic of grave abdominal inflammation.

Seventh day—general sinking, features altered, cold sweat, cold extremities and constant vomiting of green bilious liquids; abdomen distended, especially in the epigastrium and in the right flank; respirations, rapid and shallow; tumultuous action of the heart, pulse almost imperceptible; now in no pain, but could bear no pressure on the abdomen. He begged for rest and that he might only sleep. Nausea and hiccough now distressed him, but the faculties remained clear, in their full integrity.

In a state so near the impending end, no further leeching was ordered, but camphoretted blisters were applied on both sides of the abdomen, mustard to the extremities, and ether friction to the arms. Symptoms continued; death at noon—that is to say, eighteen hours after the symptoms pointing to the invasion of peritonitis.

Autopsy twenty-four hours after death.—Nothing found of special note till the abdomen was opened On opening the peritoneum a serous fluid escaped, the omentum was found congested with some adhesions. The peritoneum presented a rosy tint, more pronounced toward the right iliac region. Large plaques of a yellowish film covered the lower circle of the ileum; at first they appeared like gangrenous eschars, but they were found to consist of *discolored fibrine*, which, on removal, left the peritoneal surface intact; this material was found in various situations. A yellow bilious liquid, mixed with fecal matter, was found in the right iliac region. It was not from the intestines, but from the *cæcal appendix*.

The appendix was large, quite the volume of the gall-bladder; it was of a livid color, soft and partly gangrenous. On pressure there escaped fecal matter. A female catheter, introduced by the cæcum, came out through the opening. Its interior was irregular with various constrictions. The interior of the cæcum was natural. The stomach was distended by gas; its mucous membrane was *very* red in places; toward its greater curvature were thickening and emphysema, which we attributed to a commencing putrefaction. The intestine was also distended with gas, but its mucous membrane, except for a reddish tinge of color, was everywhere normal. The liver was voluminous and congested, the gall-bladder well distended.

Reflections.—This third case merits a moment's attention. The patient was subject to colic; it had annoyed him for some days, at first very severe, then much less; soon ceased completely, and we regarded our patient recovered; it was a perfect calm. But in the midst of this calm he is seized in the lower abdomen with the most agonizing pain, with most intense peritonitis, and prompt mortal symptoms, such as follow in *spontaneous perforations of the intestine*, but we must not be deceived by the analogy here.

I explain the divers accidents and their sequelæ here in this way: there was, first, fecal material or a calculus in the cæcal-appendix, this dilated little by little, by a sort of *obstruction*, next gangrene, then perforation. The first symptom, *i. e.* the colic, probably followed distension and inflammation of the cæcal-appendix. The rupture of the latter gave issue to extravasation, which provoked the peritonitis. This rupture might have been determined or hastened by the force employed in giving the enema; the atrocious pains began, and immediately after peritonitis set in.

This case appears to differ from that of Dr. Louyer Villermay in that there was simply inflammation and gangrene of the cæcal-appendix, while that of M. L. there was from the beginning an accumulation of fæces in the cæcal-appendix; there was rupture of the walls, extravasation and consecutive peritonitis; however, as we remarked in the patients of M. L., the cæcal-appendix was dilated to a considerable volume. As it is probable that, as in the case of M. L., there was, at first, a mass of fecal material in the appendix from an obstruction, which later provoked gangrene, with the other changes. This view seems to be borne out by the two following cases:

Case IV.—**Pain in the Right Side of Belly, Vomiting, Meteorism, Constipation. Symptoms of Internal Strangulation; Death. Accumulation of Hard Fæces in the Cæcal Appendix, Gangrene and Perforation, Thickening of the Ileocæcal Valve, Occlusion of the Intestine.**—M., aged thirty-eight, strong and vigorous, *was subject for two years to dull, colicky pains*, but never so violent as to call for therapeutics. He lived in the country on a moderate régime.

In 1825 he was called on business to Paris and had to submit to an irregular mode of living. He hastened his return, when he complained of malaise and pains in the abdomen, but not especially in the right side, and had vomiting.

Dr. Sévestre was called on June 20, and found the patient in following condition: Belly tense and meteoric, painful to the touch; pulse hard and frequent, skin hot and dry, tongue red and rather dry, continued vomiting, constipation, was bled to four palettes, emollient drinks, enemata and bath; bleeding in the evening and forty leeches to the abdomen.

June 22.—Second day of illness, augmentation of symptoms, a bleeding in the morning and another in the evening, leeches to the epigastrium and anus.

June 23.—Pulse frequent, agitation extreme, continual vomiting, enemata bring down no fæces; low bleeding—two palettes—fresh applications of leeches.

June 24.—Enormous distension of the abdomen; all the symptoms are aggravated. Dr. Sevestre did not doubt the existence of internal obstruction and gave an unfavorable prognosis. Professor Alibert called in consultation; opium and its derivatives were employed now.

June 25.—Death is now imminent. It was recorded that the mind was at no time affected. Died in the evening.

Autopsy made after twenty-four hours, in the presence of Dr. Emory.—Abdomen greatly distended by gas, intestines of great volume rolled out, of a brown-red color, and as large as the cæcum in diameter. Intestine is, in places, gangrenous, and has contracted several adhesions. *The appendix* is destroyed by sphacelas; it is nearly the volume of the index finger and presents at its extremity *a perforation*. Its cavity is distended by a hard round body, the volume of a cherry nut. It is formed of hardened fæces, disposed in layers, like a urinary concretion. The ileocæcal valve was found very thick, hard, and closed completely at the orifice of the ileum.

Reflections.—We were struck by the perfect resemblance of this and the preceding case. Both began with colic, followed by continued pain, having its special seat nearly exclusively in the *right iliac fossa*; that is to say, in the region occupied by the cæcal-appendix, the point of origin of the trouble. In both the symptoms augmented with great rapidity, in spite of energetic treatment, rapidly terminated in death.

The abdomen opened presented essentially the same conditions, to wit: the appendix distended with fecal matter, destroyed by gangrene and perforated. The relations of the symptoms and cadaveric lesions are easy to understand and interpret, in this case, as the preceding. There was in the last, as in the preceding, a slow accumulation of fæces in the cæcal-appendix, obstruction, distension, inflammation, and gangrene. In the last case there was thickening and induration of the ileocæcal valve, with the occlusion and strangulation following. This alteration in the ileocæcal valve was of long duration and interfered with the fecal current. But the inflammation in the appendix extended into, and attacked this already defective valve, it accelerated its defect and finally arrested its functions.

Case III.—**Indefinite Alteration in Health, Malaise, Diarrhœa, and Vomiting Attributed to Indigestion, Pain in the Right Iliac Fossa; Peritonitis and Death, Distension of Cæcal Appendix with Fecal Material, Gangrene.**—M. H. Vincent, age twenty-three years, strong constitution, always enjoyed good health. For two months his family noticed a change of an indefinite character; formerly gay and vivacious, he was now morose; though in pleasant society, he sought seclusion. Light exercise caused great fatigue, was tormented by thirst. Every one remarked his changed appearance; however, he claimed that he had no suffering. He ate and slept well, and gave no attention to his apparent failing health.

On March 2, 1827, about two hours after a trip into the country, where he dined, drank champagne and liquors, he was seized with malaise, nausea and vomiting. Nothing was thought of this other than that it was an attack of indigestion. He took an enema and had a large alvine discharge. He passed a restless night and was tormented by thirst, which was relieved by cool drinks.

Second Day.—M. Jacquemin saw him and attributed his condition to the fatigue and the incidents of his country visit. He then had a hot skin, a quick pulse, and thirst. Patient had vague pains in the abdomen. Cataplasms applied, enemata given, and mucilaginous drinks ordered. Passed a bad night; no sleep.

Third Day.—Had an icterus tint of face, belly distended. *The right iliac region has become the seat of intense pain*, augmented by pressure, hiccough, nausea and vomiting of green material. Thirty leeches applied to the region of the cæcum. The bites bled freely for twenty-four hours, but without relief.

Fourth Day.—Extreme agitation, pulse frequent, dry tongue, pain in the right iliac region has extended. The patient groans with distress and tosses about like one deranged, a large phlebotomy from right arm; given hot drinks, and continued enemata. During the day had vomiting of dark-colored material without fecal odor. Belly extremely tense, and can suffer no pressure; whole body now icteric, fresh application of leeches on the abdomen and sinapisms to the legs. In the evening, features profoundly altered, looks haggard, ideas confused, pulse small and frequent; blisters applied to the legs. During the night agitation diminished, speech embarrassed, patient now whispered that he had no more suffering. At 5 P.M. M. Jacquemin found him in that deceptive state of calm in peritonitis; skin cool and bedewed by a clammy perspiration; lips pale and pulse scarcely perceptible.

Fifth Day.—At 7 A.M. M. Lelinier and Anchaf Jr., gave a fatal prognosis. Death two hours later.

Post-Mortem Examination.—M. M. Lerminier, et Andral, M. Fresne, Jacquemin and Marx proceeded with the autopsy, twenty-four hours after death. They found:

1.—A purulent effusion in the peritoneum, especially in the pelvis; traces of inflammation, covered with false-membrane, everywhere.

2.—The wall of the *cæcal appendix was thickened and destroyed by gangrene.* It contained an ovoid fecal calculus, a half-inch thick, which distended its cavity.

3.—A bridle of fatty tissue extending from the mesocæcum to the abdominal wall. The bridle was so placed as to envelop the cæcum and narrow its cavity. Everywhere the cæcum and appendix were bathed in pus and false membrane.

The gastrointestinal mucous membrane showed no signs of intense inflammation. The intestines were all distended by gas.

From this examination the council of physicians concluded, 1st, that the cause of death was abdominal; 2d, that the calculus, found in the appendix, was proved by its consistence and other characters, to have existed a long time, and had progressively led to trouble in function; 3d, that the appendix was at first irritated by this calculus, which had provoked an inflammation, promptly terminating in gangrene, and that the extending peritonitis had determined a mortal phlegmasia.

Reflections.—The explanation conforms with what we have observed in the preceding cases. They were essentially similar; in all the symptoms bore a striking relation to the lesions found.

It was evident that in the three last cases the accumulation of fæces, irritation therefrom, inflammation and obstruction preceded gangrene and perforation.

The third and fourth cases began by *colic*, with vague pain in the abdomen, *and acute distress over right iliac region.* The dominant symptoms of acute, intestinal obstruction were manifest here.

If this succession of accidents is constant, it may, perhaps, permit us to distinguish—two stages in the march of this disease. The first, characterized by colic, corresponds to the dilatation of the appendix with fecal matter; second, an nounced by severe pain in the ileocæcal region an effusion into the peritoneum, or an acute peritonitis corresponds with the moment that the over-distended inflamed appendix is destroyed by gangrene and ruptures. However, in the present state of things, it must yet remain very difficult to recognize the types of disease of the appendix which we have described.

Happily, this malady appears to be rare, although these four cases have occurred in a short period.

There are two, by the same physician, which leads us to believe that if this disease has not been oftener observed it is because inadequate attention has been given to the ileocæcal region, to that organ regarded as unimportant, so that even on autopsy one neglects to scrutinize its lesions.

We may add that Dr. Sévestre, who was called to the second case in consultation, has informed me that he was able to pronounce it disease of the cæcal-appendix, because it was characterized by quite the same symptoms as in the first patient. In all the cases the malady pursued a rapidly fatal course toward death.

If it were possible to establish an early and definite diagnosis in this malady in these well circumscribed cases, one can conceive of the possibility of relieving them by an operation. No doubt this day will come. Physiological experiment should be appealed to, to clarify this question and elucidate the pathology. It would be interesting to study the various types of the disease by experiments on the cæcal-appendix. If the foregoing notes have been read with some attention, one cannot but regard this subject as worthy of serious research.

Case 6.—**Perforation of Cæcal-Appendix with a Communication Externally through a Fistula in the Right Iliac Fossa.**—Patient, male, forty-five, slim in stature, one hundred and ten pounds, subject to frequent and prolonged catarrhal affections In 1812 was seized with severe pain in the right iliac fossa, a large tumor presenting; sensitive to the least pressure; constipated; meteoric belly and febrile state.

This disease depended on an effection of the cæcal appendix, with impaction of fæces; was treated tentatively by prolonged baths, topical applications and severe dieting. Pain and fever ceased. Constipation was overcome by senna, and very large, offensive evacuations followed. Sulphur baths, careful regimen. Asses' milk, which, with simple food, led to a cure or a great improvement in his general condition. This improvement continued until February, 1815, when M. Malas was again called to treat a pulmonary affection. The patient recovered from this and returned to his usual occupation, when he was seized with violent pain in his *right iliac region.* The cæcum appeared to be of considerable volume, exquisitely sensitive. The patient had constipation; was given repeated baths, warm drinks, and castor-oil. The weight of a cataplasm was in tolerable. There was little change till the 13th of March; the tumor continued in spite of free evacuations or stercoraceos discharges, and showed no diminution in volume. It was thought that the tumor occupied the intestine itself.

Inflammation became more and more pronounced; the tumor was harder, irregular and more prominent; it was located in the right iliac fossa. MM. Jacquemin, Sr., and Dupuytren were called in consultation.

on March 14. Fluctuation was discovered. M. Dupuytren made an opening, from which there was a large issue of pus of a fecal odor. There was immediate relief. The wound remained unclosed, a fistula followed, from which a great quantity of pus escaped.

Three new openings were spontaneously made, all communicating with the first.

This state continued until the winter of 1816, when the pulmonary condition became worse and dropsy appeared in the limbs. It may be recalled that when the discharges diminished diarrhœa set in, to again abate when pus escaped from the fistula.

Finally, on April 15, the patient taking cold, was once more seized with abdominal pain, and succumbed to acute peritonitis.

Autopsy following day by MM. Jacquemin, Sr., and Jr., with M. Nacquart. The body was greatly wasted, extremities œdematuds, thorax resonant, belly somewhat distended, a collection of pus occupied the summit of the right lung. The peritoneum contained about three liters of serum, in which floated flocculi of discolored fibrin, the surface of the intestines was highly inflamed. On examining the right iliac fossa, the intestine was found to communicate with one large sac, this adherent to cæcal-appendix, which was here opened. The cellular tissue in the iliac fossa was healthy, also the cæcum and colon. The fistula showed signs of closing.

In spite of the communications between the cæcal-appendix and the abscess cavity, pus never appeared in the fæces nor the fecal matter in the fistula.

Reflections.—Thus comparing this case with the preceding, I am compelled to believe that the cæcal-appendix was the seat of the *primary disease*; that the primary trouble was impaction of fæces, in the appendix, perhaps, a stercoral calculus, as in the fifth case, that this provoked adhesive inflammation within the peritoneum, that the cellular tissue became engorged and finally the appendix opened, here a phlegm forming. It is just possible, however, that the abscess formed first, and later opened into the appendix. Before closing this memoir on diseases of the cæcal-appendix, we will add a few other notes which we have read.

They are by Dr. Lewis, vice-president of the *Société de Médecine*, they constitute the text of an essay published in the *Bibliothèque Médicale* (1814 v XLIII, p. 333).

CASE VIII.—**Ascarides-Lumbricoides Found in the Cæcal-Appendix** (From a clinic by M. ladolot in 1808.)

A youth of thirteen years died on the tenth day after his entrance into hospital from a disease treated as *adynamic fever*, and who in his last days presented some symptoms of *ataxia*. On opening the body it was discovered that the end of the ileum, the cæcum and appendix, were filled with lumbricoids.

Case VIII.—**Stercoral Calculus in the Cæcal Appendix; Inflammation of the Appendix, Gangrene of Cæcum.**—A young man, eighteen years old, of strong constitution, complained for some time of colic—at first trivial, but later severe. After three days' suffering a physician was called. He discovered *severe pain* in the *right iliac region*, occupying an area equal to the palm of the hand; augmented on the least pressure, belly distended, constipation preceded by moderate diarrhœa, hiccough, nausea, followed by vomiting, at first bilious; after twelve hours fecal; aspect of the face and eyes presaged delirium; tongue moist, pulse irregular. Following day, prostration of strength, features altered, *no pain*, marked meteorism, pulse weak, constantly vomiting of fecal fluids, delirium tranquil, extremities cold. Patient succumbed quietly in the evening.

Post Mortem.—On opening the cadaver, inflammation of the ileum at its junction with the cæcum, with gangrene, appeared. This condition appeared to start in the cæcal-appendix. *Cæcum ipsum a gangrenâ destructum erat, quæ omnis ab ea parte, ubi processus-vermicularis illi se inscrit. Exorta esse videbatar.* The appendix was of a red color, larger than natural, its mesentery injected was adherent. The appendix contained several calculi. These calculi were sent to the *Société-Médicale d'Emulation*, where they were analyzed by M. Robiquet. The largest was ovoid in form and weighed a grain. The others were nipple-shaped and spurred, they presented an aspect of marble calculi; their odor was fetid. They were found to consist of 60 per cent. of fatty matter, 30 per cent. of phosphate of lime, 8 per cent. of animal matter; their general characters were those of biliary or bladder-stones. These calculi were the primary cause of inflammation, the disease beginning in the appendix.

We note in this history that the principal symptoms were first a *moderate colic and later intense pain, continued and circumscribed in the ileocæcal region.*

This is noted by the author himself, that the gangrene seemed to first manifest itself from the side of the appendix. We were able to find but one case recorded similar to Wegler's; this was published by Amgand. A needle found the center of a calculus. *Unicus tantum casus, ubi acus, crusta lapideâ obducta in processu-vermiculari detecta fuit.* Vicg. d'Azir has cited an analogous example (Enclycopædic Method, ii, p. 286), the concretion being as large as a hazelnut penetrated in the center by a *hair.* Finally, there appeared a report by M. Oliver Prescott—*Gazette de Saté*, January, 1817, p. 13, of a similar case, death occurring in the presence of symptoms of peritonitis.

On autopsy a concretion as large as a walnut was discovered in the cæcal-appendix; gangrene extend into the ileum and cæcum.

In conclusion we wish to say that M. Louyer Villermay was the first to call the attention of physicians to disease of the cæcal appendix, and impressed the importance of the pathology of an organ of which up to that time we know little.

Inferences from a Review of Mélier's Contribution.—At the onset, we note the striking analogy to the experience of Lambert, who first discovered the secret of artificially inducing intestinal adhesions—*serosa ad serosa*—by the employment of suture in 1823. His deductions as to the utility of this procedure on the human being were entirely based on his experimental observations on the lower animal, as during his life no opportunity ever came to him to test their appreciability in the surgery of the intestine of man; and so with Mélier, who, seventy-five years ago, struck at the very foundation of the pathology of diseases of the appendix and clearly prophesied their ulterior and only rational treatment by surgery; it does not appear that he ever had a case which he recognized as this malady himself.

Nevertheless, he has left posterity in his debt for not only by laboriously gathering cases from widely separate sources and classifying them, but also for bringing the radiance of logical scientific reasoning to bear on their unique and special characters.

Indeed, his brochure clearly demonstrates that he was far ahead of his time, as his classification of cases and his efforts to correlate destructive symptoms with pathological changes and prove their reciprocal relations, demonstrate. Moreover, the thought had clearly dawned on him that in order to prevent disaster from a spread of the infection, it could be only accomplished by dealing with the immediate seat of disease. He emphasizes that because this "vestige" has no functions, anatomico-pathological research on its pathology was omitted, it appeared to serve no purpose in the economy, hence its pathology was regarded as insignificant. His citations from Bèclard, Bichat, and Meckel warrants the inference that long before his time physiologists and surgeons had made an experimental study of the appendix on lower animals; that they had so far perfected operative technique on it as to obviate its dangers. Anæsthetics and asepsis only made it safe or expedient to transfer these experiments to man when they were first safely tested by Dr. Henry B. Sands in New York in 1882.

Dr. Mélier graciously accords to Villermay full credit for "being the first to call attention of physicians to disease of the cæcal-appendix and impress the importance of the pathology of an organ of which up to that time we know so little. But on an examination of Villermay, original brochure of 1826, we find little more than the details of his own two cases, without any attempt at an exhaustive consideration of the subject; Mestivier reported a case of peritonitis from perforated appendix in 1759."—*Journal de Méd. et Chirurgie*, 1760. Celsus in his description of ulcerations in the large intestine, observed that the cæcal-end was the most common seat.

In the beginning of the eighteenth century the physiologists, Ambry, Boerhave, and Morgagni, began an experimental study of the functions of the appendix, but went no further.

Deaver, in his treatise on "Appendicitis," says: "Mélier was the first to draw conclusions from a number of observations in 1827, and in 1833 Dupuytren recorded observations which led him to believe that there was a connection between the abscess and the cæcum, and as it was largely due to this authority that the cæcum was so generally accepted as the primary seat of the disease."

Monod divides the history of the pathology of appendicitis into three periods: (1) The discovery *pour aussi dire* by Mélier; (2) It was denied that the disease originated in the appendix, but it was alleged that it commenced in the cæcum; (3) All agree that the appendix alone is the site of primary changes (*Appendicite*, par MM. Mond et Vauvarts).

An Analysis of Cases.—From an examination of Mélier's series, we note (1) That they were all males; (2) All of robust frame; (3) All acute cases of the fulminant type in the first five cases; (4) They were all primarily dependent on fecal impaction and gangrene of the appendix. One of the remaining three was evidently *chronic*, and complicated by tuberculosis, the last was also acute.

Mélier's graphic description of the first series is a classical portrayal of the progress of acute peritonitis of grave type. The accurate and detailed enumeration of symptoms is one of the most valued features of his notes, something which might be imitated with advantage by many of our authors of textbooks.

The feature of strong retraction of the right testis in the *first* case with the cold foot on same side for four days was somewhat remarkable. In this case we note the *calm*, after energetic treatment. He notes this deceptive truce in others. This is the *interval*, the time when, if at all, we should freely cut down on the appendix. We note here the time-honored poultice, the mustard applications, the enema and, the most prominent of all, the free depletion by "leeching" from its well-known influence on incipient inflammatory affections.

The notes on the autopsies emphasizes what Mélier insists on in all cases, viz., that the appendix alone showed signs of destructive pathological changes, an organ without function was capable of very quickly destroying life.

Case II. points to the sudden onset of the disease and the reflected character of the pain in the beginning. Cramps in the calves. Pain in the right iliac-fossa, with fullness and tenderness later. Patient had a reducible hernia.

The "phlogosis" of the stomach was the only evidence of diseased action, independent of the appendix. The disease ran a mortal course in thirty-six hours. This case evidently called for the scalpel early. A large fecal concretion, encircled by an area of gangrene, was disclosed.

Case IV. bears out Mélier's theory of pathological action after fecal impaction and consequent irritation, obstruction, gangrene, perforation and peritonitis, with effusion and death. Here we find a marked abatement of the symptoms on the sixth day, with every prospect of an early recovery, until all hope had vanished, *after* an ill-advised enema. In this instance there can be no doubt, but the injected fluids over-distended the cæcum, widely opened the gangrenous appendix, and polluted the peritoneal cavity by foul fluids and noxious gases. This case well illustrates the dangers which may attend or follow large and forcibly injected enemata in acute appendicitis.

"The instant the enema was given atrocious pains began and peritonitis set in."

Case IV. was complicated by rigidity and thickening of the ileocæcal valve, and intestinal obstruction; the pathological condition of the valve, it appears, was of a chronic character, intensified by a spread of infection from the rotten appendix. In this case we read for the *first* time that *opium* was administered.

This case is notable in again presenting that symptom of *malaise*, those changes of an indefinite character so often witnessed by keen observers for a time before appendicitis sets in; its prodromal stage.

The patient has lost his grip, is indisposed and easily fatigued, but is fain to admit it; he plods on with his labors, and only takes to the bed when the third stage is reached and perforation occurs.

Case V. was one pursuing the typical course of gangrenous perforation. Mélier pertinently points out here that this malady is of much more frequent occurrence than is supposed, and is not discovered because of an inadequate examination.

Priority in diagnosis of this disease, it appears by the testimony of Mélier, belongs to *Sévestre*, who saw Villermay's second case.

Case VI.—This strikes one as the most notable of the group. Malas's case was of the chronic, tuberculous type. On March 14, 1812, Baron Dupuytren "made an incision" in this case. This appears to be the *first* operation for an appendical-abscess on record, although we have no evidence that this celebrated surgeon had a proper conception of the pathological conditions present.

The case was one of multilocular abscess, with diffuse pus formation, as these were later found in the openings, after the incision was made. Lack of healthy plasticity in the tissue, rendered effective repair impossible, with that sometimes troublesome sequla, fistula, following. No pus was found in the discharges from the rectum, nor any fecal fragments in those from the wound. The microscope had not yet come into use, and hence why the results of this examination are wanting.

Case VII.—The one of "adynamic fever" does not properly belong to this group, though there are cases on record of lumbricoids having been found in appendical abscess.

Case VIII.—Belongs to the serious acute form of the appendicitis, its various stages being quite clearly defined.

Symptoms and the pathological anatomy of appendicitis are described with singular clearness in the Mélier's essay, written three-quarters of a century since. He divides the clinical history into four distinct stages; the first, even our latest and fullest writers have failed to amply emphasize—the period of malaise, with the sense of fatigue, the flatulence and vague pains through the abdomen; the second, the period when the local objective signs of the disease are manifest, the fullness and tenderness over the right iliac fossa, with coincident severe systemic disturbances—the colicky pains.

The third period is described with singular accuracy.

Mélier now points out that the storm is on, the explosive stage is reached, the mortified appendix has opened and the intestine leaks into the peritoneal cavity, when the rupture is large and adhesions have not formed. The symptoms of septic peritonitis are now set forth; the insatiable thirst, the incessant green vomiting, the agonizing pain, loss of sleep; the abdomen is now hard and meteoric, and everywhere hypersensitive.

The fourth period indicates the approach of the moribund state, the settled calm, the clear mind, the absence of pain, the cold and livid extremities, point to death beginning at the periphery.

Melier aimed to connect symptoms with pathological changes, and accomplished his purpose with most convincing effect. In this direction he has left practically nothing for his successors to elaborate on.

The "circumscribed" cases, if diagnosed definitely and early, he thought might be saved by surgery. This is precisely the view of the very latest writers. There are the encysted cases; pus is walled off by adhesions, and all are agreed that the only thing to do is to freely open down, evacuate the pus, and, if expedient, remove the necrotic appendix at the same time. He insists on the supreme importance of animal experimentation as a means of elucidating therapy; and reasons that if we can remove the appendix of an animal with safety, we should do the same in the human being.

Indeed, we must conclude, from the intimations of Mélier, that long before his time several of the most noted anatomists and physiologists had given the structure and diseases of the appendix extended study. Robiquet had determined the chemical composition of appendicular calculi and showed this structural similarity to other conditions.

I have been unable to secure the detailed account of Prescott's case recorded in the *Health Gazette* of London.

Phophylactic appendicectomy, it would appear, from the foregoing brochure of the French surgeon, to be not only justifiable, but a rational and necessary procedure.

He calls our attention in the beginning to the fact that this vestige or *culdesac* is destitute of function, and, this being conceded, no one conceived that it could be the seat of pathological processes; in other words, that there could be *no* pathology in a structure devoid of physiological uses.

Now that it is known, beyond all doubt, that it serves no purpose except for mischief, the early and universal removal of the appendix is called for.

It ought to be as generally performed as vaccination is practised; for, on the whole, appendicitis destroys more lives than smallpox, and various painful types of it are very common. Appendicistomy is certainly a more necessary procedure than circumcision, and in young, healthy adults should have no mortality whatever.

In considering the question, traditional conservatism, we must make way for conclusions based on the revelations of progressive science. Talamon speaks of the appendix as *un organe inutile et nuisible*, and Treaves declares it "obsolete and out of date, and the man of the future will have no such structure hanging from the cæcum" (Lockwood "Diseases of the Appendix"). This author notes that in England George Southam, a Manchester surgeon in 1835 recorded the first case of suppurating appendix. This report was published in 1840. And Kelynack—*Pathology of Vermiform Appendix*—records the case of perforation of appendix from fecal infection in a boy in 1812, submitted at Medico-Chirurgical Society of London.

EAR COMPLICATIONS OF MEASLES AND THEIR TREATMENT.[*]

By HERMAN JARECKY, M.D.,
NEW YORK.

VISITING OTOLOGIST, HARLEM HOSPITAL, AND ASSISTANT SURGEON, MANHATTAN EYE AND EAR HOSPITAL (EAR, NOSE, AND THROAT DEPARTMENTS).

In the short time at my disposal it is not possible to treat this very serious subject minutely, but simply to point out the most important details, and such treatment as is useful to the general practitioner.

The ear complications of measles are usually light, and progress to recovery, but a certain number leave serious defects. Roosa[†] ascribes deaf-mutism in seven cases out of 147, and James K. Love[‡] ten out of eighty-one, as being due to this disease. A number of other patients are afflicted with decreased audition, with or without some chronic diseased condition.

In considering the etiology there is no doubt that the mucous membrane of the auditory apparatus partakes of the general catarrhal condition and eruption of the exanthem. So also does the general poisoning of the disease affect the organs of hearing. Bezold[§] found post-mortem evidence of this as early as the first three days of the eruption.

The suppurative condition is due to a mixed infection, which is easily propagated in a system weakened by disease.

The microorganisms found are the streptococcus pyogenes, staphylococcus pyogenes, albus aureus and vitreous, Fraenkel's pneumococcus or diplococcus, and Freelander's pneumobacillus.

The streptococci and the pneumococci are found to do the most mischief. Bacteriological diagnosis will undoubtedly be the guide in the near future, as to prognoses and to operative procedures.

Other cases are due to extension from the postnasal space through the eustachian tubes, and principally found where the vault of the pharynx is occupied by hypertrophied lymphoid tissue. This can be easily understood, when we consider that

[*] Read before the Society of the Alumni of the City (Charity) Hospital.

[§] 3. *Zeitschrif furt Ohr*, XXVIII.

the increased secretion, on account of the patient's horizontal position, cannot escape easily, and so helps to block up the opening of the tubes.

In considering the complications we find in the external ear and canal when large papules, exist and become confluent, there is a feeling oftension, which, however, wears off, as desquamation occurs.

The acute otitis media, either catarrhal or purulent, may occur at any time during the disease, but generally while fever is present.

It may be either unilateral or bilateral. Although both ears may be affected simultaneously, one may heal more rapidly than the other.

The catarrhal form usually occurs with light attacks, although the reverse may be the case. The discharge is usually turbid from the presence of epithelial cells, and rather viscid from the mixture of mucus.

The purulent is generally associated with severe cases, and often results in destruction of the ossicles and tympanic walls.

In the catarrhal variety the patient, especially an adult, complains of pains, varying in character from a dull ache to one that is sharp or lancinating. Temperature is, as a rule, negative. The hearing power is diminished. In infants and children, who cannot direct attention to the spot whence the trouble arises, any increase in temperature, fretfulness, restlessness, burying the head in the pillow, or putting the hand to the ear, should call attention to that organ. Very often a discharge is the first sign of the trouble.

In purulent cases the pain is usually more intense, being often excruciating in character. The temperature is, as a rule, high, rising to 103°, sometimes higher, pulse rapid. There may be vertigo, tinnitus, headache, constipation, and anorexia.

In infants and children the symptoms are usually much more marked; the temperature high, 104°, pulse exceedingly rapid, convulsions, delirium and coma may be present. After the appearance of the discharge, the constitutional symptoms usually abate and the patient falls quietly asleep. If there is a recurrence of the symptoms, the parts should be carefully cleansed and inspected, and free drainage established.

I have found in children, even where free drainage exists, a recurrence of temperature for a few days. This is due to an early rupture of the drum membrane before the inflammation in the tympanic cavity had run its course, or it may be due to the presence of the hypertrophied lymphoid tissue in the vault of the pharynx.

In severe cases the inflammation often extends to the mastoid, filling the antrum with pus, and causing considerable bone destruction from the acute caries. The temperature in these cases usually shows some increase. The pain may be of marked severity, or of a light character. The discharge diminishes in quantity. Facial paralysis may occur. There is tenderness usually on pressure over the antrum, that is at the attachment of the auricle close to the superior wall of the canal. Sometimes this is most marked over the mastoid tip. If there is a perforation of the mastoid cortex, there will be fluctuation over the bone. In infants the pus often escapes through the Rivinian segment having made its way along the superior wall of the canal, and there is a postauricular swelling, making the ear project out more prominently. There is invariably present a marked swelling of the superior posterior canal wall. A perforation may take place on the internal surface of the mastoid when a brawny swelling will extend along the Sterno Cleio mastoid. If the pus passes to the cerebrum or cerebellum the following are the symptoms: Pain in the head, drowsiness, or violent delirium, disordered speech, convulsions, optic neuritis, vomiting, constipation, pareses of various kinds. These are due to an extra-dural abscess, leptomeningitis, abscess of the temperosphenoidal lobe or one of the cerebellum. When one of the large sinuses of the dura mater is involved, symptoms of pyæmia appear. Labyrinthian complication, without much effect on drum membrane, presents more or less pain, dizziness, nausea, troublesome tinnitus, and hearing power impaired or lost on one or both sides. Fortunately, this is of extremely rare occurrence.

In examining an adult the auricle should be pulled upward, backward, and outward in order to straighten the canal. In children the canal is straight, and the membrane easily inspected. In infants the lobe should be pulled downward and outward, and we should look upward.

The examination of the drum membrane in the otitis media conditions will show more or less congestion. One must not be deceived if the membrane is of a dead white color. This is sometimes due to necrosis of the superficial epethelium which can be easily removed by a cotton-tipped probe, when the reddened membrane can be seen.

For pain in adults relief is often found by abstraction of blood, applying natural or artificial leech over the traugas. A hypodermic injection of morphine will often cut short an attack. Occasionally I have had results from phenacetin, 5 to 10 grains, or acetanilid, 2 to 4 grains, every two or three hours. The local watery solution of morphine, cocaine and atropine have never been satisfactory. Oils are only mentioned to be condemned. Glycerine, with 5 to 10 per cent. of carbolic acid, applied on a cotton to the drum membrane, and allowed to remain from six to twenty-four hours, often cures the pain. This can be repeated if necessary. Dry heat is very effective at times. Moist heat causes œdema of the tissues, and should not be used. Frequent irrigation with hot water from a fountain syringe, placed about one foot over the head, using about a half to one pint of water, is often efficacious. The nose should be kept clear by irrigation or swabbing, and a gargle used to dispel any mucus from the throat. The bowels should be carefully looked after.

If the attack is not aborted, the hyperæmia increases, and the membrane loses its lustre, causing a general swelling and bulging.

This should not be allowed to perforate spontaneously, as the rupture is jagged, and causes irregular cicatrices, and takes a much longer time in healing, than when incised, and the prognosis as to the future hearing is worse. Only in extremely few cases do we see good results.

When bulging exists paracentesis should be at once performed. For this operation the canal should be cleansed; either irrigated with bichloride solution 1 to 5,000, or else mopped out with peroxide of hydrogen.

Then with a good light, the knife should pass through the bulging portion, or from the point behind or below the stapes to the lower border of the membrane close to its bony attachment, by a curved incision, that is the posterior inferior segment. The knife I prefer is a straight one, but one at an angle may be used. It must be exceedingly sharp, and should pass through the membrane by its own weight, incising at the same time the mucous membrane of the internal tympanic walls to secure thorough depletion. If the membrane has ruptured spontaneously, the opening should be inspected to see that there is sufficient drainage, if not, a free incision should be made. For local anæsthesia I have found cocaine to be of little value. Aniline oil* and cocaine have

*4. Dupuy, "Laryngoscope," October, 1901.

given toxic symptoms. The mixing of equal parts of menthol, carbolic acid, and alcohol, has only been occasionally satisfactory. In adults I invariably use nitrous oxide, and in children chloroform or ether. Infants can be held firmly and operated upon.

After the operation I irrigate, pack the canal lightly with sterilized gauze, put a pad of cotton over the ear, and retain all with a bandage, which I leave undisturbed for twenty-four hours, directing the patient to lie on the side affected to facilitate drainage. If there is much discharge at the time of incision I order douching.

When the gauze is removed I order irrigation, according to the amount of discharge. Some cases heal up in a few days.

The discharge which is usually at first serous, later often becomes purulent and profuse. The cleansing may be needed every two or three hours. Saturated solution of boric acid, bichloride 1 to 5,000 or 10,000, or sterilized water, may be used. As the discharge diminishes the cleansing should be reduced in frequency.

A second method of treating these cases, when they can be watched closely, is to dry the middle ear with cotton, introducing strips of gauze daily for drainage, and a pledget of cotton is put in the external ear.

A third method is to clean out the ear with a syringe, then use peroxide of hydrogen and finish by syringing again. The ear is mopped out or dried with repeated distillation of alcohol, diluted, if painful in its full strength. When painful symptoms stop, inflation either with eustachean catheter or pollitzer bag helps to get rid of the pus, and to prevent adhesions.

The use of powders as boracic acid, iodoform, dermatol, etc., is excellent when the discharge is slight. Then after cleansing an insufflator should be used, care being taken not to block up the perforations. These may remain in until moistened by the discharge.

If the condition becomes of a chronic nature, various astringent applications can be used, either applied with a swab, or in the form of drops. Inflation should be employed, granulations should be cauterized and polypi snared.

If symptoms point to mastoid involvement, I order frequent irrigation of the canal, Leiter's coil or ice bags over the mastoid continually for twenty-four hours. Rest in bed, light diet, and cathartics.

There must be free drainage from the tympanum at the same time. If the membrane is incised, it is always wise to incise the posterior superior canal wall for one-fourth inch down to the bone.

I give no opiates to disguise symptoms, when pain still continues I operate. If pain ceases, I stop the coil or ice bag for twelve hours, then reapply for twelve hours, and judge result.

I employ no leeching over mastoid as it prevents proper examination for tenderness. The brain and sinus complications with the description of mastoid operations, the time permitted does not allow me to touch upon.

There is no doubt, if in the early stages the drum membrane is watched and incised promptly, many of the later complications could be avoided. The incision of the membrane is simple, and has been the means of saving many ears from becoming defective.

So I close impressing the importance of having the nose and throat looked after in all children, and advising an early incision of the drum membrane, if needed, or if in doubt.

115 West 121st Street.

SOME POPULAR OBJECTIONS TO VACCINATION.*

By WILLIAM R. FISHER, M.D.,
SWIFTWATER, PA.

There never has been a time since Jenner's discovery when vaccination has met with universal, unqualified acceptance; but probably at no period has it stood in such disfavor with the public at large as it does to-day. A glance at the situation will satisfy the most casual observer that throughout our country the feeling of opposition against vaccination is not only widespread in extent, but that it is growing in intensity. Muttering discontent is rapidly assuming the proportions of open and forcible resistance, and sanitarians realize that they are confronting one of the most difficult and serious problems of the day.

In approaching the solution of such a troublesome question a long step forward may be accomplished if disputants show a disposition to take an all-round view of the subject, and, mutually recognizing the grounds of difference, set to work to clear away the barriers which keep them apart. But the man of science is too apt to be so dogmatically sure of his own position that the criticisms and censures of the unlearned affect him not at all. Yet he must learn that if he expects to deal successfully with such a subject as the popular objections to vaccination he must step down from his rostrum and take a comprehensive look from the humbler standpoint of the common people. In the first place he must remember that the knowledge which he possesses concerning the prevalence of smallpox, and the frightful devastations which it wrought all over the world before Jenner published his immortal discovery is not shared by the people at large. It belongs exclusively to the educated. For, in spite of an immense amount of statistical evidence and theoretical preaching on this point, no appreciable impression has so far been made on the public mind. The severe epidemics, which in olden times used to sweep over large expanses of country, killing off thousnds and branding the surviving victims with the scars of loathsome disease, gradually became mere matters of history. The pock-marked faces which used to be met with everywhere, hideous reminders of an ever-present danger, were seldom seen. And the public, enjoying the advantages of a preventive agency of incalculable value, naturally came to regard the new condition of safety as a matter of course. The old terror of smallpox and its dangers passed away and a careless indifference took its place. The family physician began to note a growing tendency among his patients to give up the old-fashioned custom of infant vaccination, and to put off the procedure until the child had reached the school age. Secondary vaccinations became more and more infrequent.

The consequences of this apathy were inevitable. When a large percentage of the population was unprotected, outbreaks of smallpox were certain to occur. The disease reappeared from time to time during the last century; but, succumbing to the potent energy of vaccination, became quiescent, only to burst out again when a thoughtless public, lulled into a false sense of security, abandoned the use of the means which brought it protection. The story has been repeated over and over again, teaching valuable lessons to those who were capable of learning, but passing unheeded by the ignorant. To the latter the frequent reappearances of the disease only seemed to show that vaccination did not furnish the much-vaunted protection which its advocates claimed for it. To sanitarians, on the other hand, repeated outbreaks proved beyond doubt that safety for the people could alone be found in more thorough application of the remedy. Knowing that smallpox would practically be eliminated from the face of the earth, if the people could all be induced, or, failing that, be forced to submit to proper vaccination, the guardians of the public health began to work for more stringent legislation and more effective enforcement of laws already existing. And here the placid indifference of the people began to ripen into active antagonism.

---

*Read at the ninth annual meeting of the Associated Health Authorities and Sanitarians of Pennsylvania, at Butler, Pa., May 7 and 8, 1902.

At this point it may be well to indicate the part which the science of bacteriology has played in helping on popular dissatisfaction over the attempt of the sanitary authorities to extend the practice of vaccination. To speak more correctly, it is not the science of bacteriology that is at fault in this particular, but rather the crude and imperfect notions about it which the people have absorbed for the most part from the current press. Bacteriology is of such recent origin, and its growth so rapid, that there has not been time nor opportunity to systematize its facts or to generalize its conclusions, in a manner that would be suitable for popular understanding. With that little knowledge that is known to be so dangerous the wildest inaccuracies are being gravely passed about and accepted without question as the latest scientific dicta. The word "germ" is, for the time being, the bogey-man of grown-up children, whose vague and indefinite terrors may be summed up in an indescribable fear of "microbes" and a wholesome dread of "blood posioning." People whose grandmothers complacently poulticed suppurating sores with equanimity and satisfaction, no longer look on festering vaccination without apprehension.

Recent events have transpired in certain cities that could not do otherwise than shake the confidence of the people in the use of biological products. The occurrence of cases of tetanus after the use of antitoxin and vaccine virus has frightened a great many into a belief that it is better to bear the ills they may possibly have than fly to others which they think they know all about through the newspapers. Such deplorable experiences are, fortunately, very rare indeed, but they serve to furnish material for outrageous attacks upon protective medicine to which a credulous public is too ready to listen. In this connection, however, it is well to remember that the strength of the anti-vaccinationists is not in exploiting the occasional fatal case, but in working upon the fears of the people over the minor complications which so often follow vaccination (the ulcerations, the sloughs, and so on,) always accompanied by pain and discomfort, and now and then by serious consequences. It cannot be denied that, with our knowledge of bacteriology, such sequels to vaccination ought not to be met with. Infection is the cause of these complications, and we know that infection can be prevented. With all our claims of aseptic vaccine virus and aseptic methods, it is questionable whether vaccination, as it is generally performed at the present time, is one whit better in its course and results than it was in the old days before the coming of Pasteur and Lister. In that pre-microbic era when humanized virus was in vogue, the "sore arms" and sloughs and indolent ulcers were probably not much worse nor more frequent than they are at the present time. We talk about aseptic vaccine virus and aseptic vaccination, but very little is heard about aseptic after-treatment; in fact, very little is heard about after-treatment of any kind. Physicians do not seem to appreciate that it is useless to secure the purest virus and to use it with all the details of aseptic surgical procedure if the operator intends to drop the care of his case at this point. Without protection of the site of vaccination infection is pretty sure to follow. In fact, so common is it that it is quite the usual thing (among physicians as well as laymen) to consider an infected or "sore arm" as synonymous with a successful take. A grave responsibility rests upon those physicians who fail to convince the people by practical demonstration that complications after vaccination are the result of infection; that infection is preventable; that vaccination is a surgical procedure requiring care and after-treatment, and that, having these, it is as harmless as it is beneficial. If all would do their duty in this regard much would be done to check the spreading disaffection, and to put a stop to the clamor of the professional anti-vaccinationists. Of these latter, it may be said without harshness, that the honest ones among them are ignorant of the facts about vaccination, and those who know the facts are not honest in their opposition.

The weight of evidence in favor of vaccination is so overwhelming in its logical force, that the one who honestly fails to accept its conclusions must either be grossly ignorant or else incapable of reasoning. This sweeping assertion appears to be the rock on which the warring factions come to grief. No matter how true and unanswerable the statement may seem to be to the trained mind of science, it does not follow that a reiteration of it will carry conviction to the minds of the unlearned public. To call a man an ignoramus or a fool is not the way to promote the amenities of argument, nor will it conciliate the impartial bystander who is interested in the discussion and ready to be convinced. The first thing to attract the attention of such an observer would be the woeful lack of agreement between the different parties who make up the supporters of vaccination. Where he might expect to find union he would find discord. Discussion on every point and agreement on none. He would notice the producers of vaccine virus wrangling among themselves with bitter enmity over the qualities of their various products. Turning to the physicians who employ the virus, in the expectation that experience would enable them to decide the points upon which the producers were at variance, he would be surprised to find a similar state of disagreement. He would find them differing about lymph virus and glycerinated virus; about the mode of operating; about the number of insertions; about the necessity of repetition, and even about the signs which indicate a successful vaccination. On this latter point he would hear the statement freely made that numbers of physicians do not know how to determine whether a vaccination has been successfully performed or not. With such an exhibition of disunion on the part of the supporters of vaccination, it does not surprise him to find that there are some physicians who go still further and denounce vaccination in toto; assailing it as a dangerous practice, corrupting the blood and sowing the seeds of fatal disease. He would discover that in the eyes of the law the status of some of these recalcitrant doctors was just as good as that of the most distinguished college professor who proclaims the discovery of Jenner to be the greatest boon that humanity has ever received at the hands of man. It is the old story of the disagreement of the doctors. Who, indeed, shall decide? If our simple citizen is unable to do so after his contemplation of this dismal spectacle of professional dispute, and should make up his mind to keep his child unvaccinated until those who profess to know all about the matter come somewhat nearer together upon a common ground of agreement, can he be said to be altogether unreasonable? It may be said in answer that he is ignorant and, therefore, has no right to an opinion on the subject. If so, then all the greater is the burden on those whose duty it is to enlighten him. Among the forces that rally to the support of vaccination our honest observer would soon notice a faction whose restless activity has of late been pushing it forward into prominence. It is the party that favors compulsory vaccination because it sees in the growing spirit of popular resistance a senseless opposition to the public welfare which can only be subdued by legal enactment. The evidence is abundant to prove the good results that can be accomplished by means of compulsory vaccination. In Germany, for instance, under stringent laws, statistics show a percentage of cases of smallpox so wonderfully low when compared with those of other countries where compulsion is not resorted to, that no doubt can exist as to the benefits which would follow here upon the enforcement of similar legislation. Compulsory vaccination is, therefore, proposed as a solution of the whole difficulty. It would put an end to all opposition by putting an end to smallpox—a consummation devoutly to be wished. But what are the signs of the times? Within a few months, in a neighboring State, the advocates of a bill to make vaccination compulsory have been utterly routed before a legislative committee by a vigorous onslaught of an anti-vaccination society. In another State the force of public opinion, under intense excitement, has been sufficient to compel the health board of a large city to abandon all attempts to enforce the law requiring vaccination as a requisite for admission to the public schools. Such instances show the trend of popular feeling against arbitrary laws and despotic measures. There is no more reason to suppose that our people would follow the German example and submit quietly to compulsory vaccination than to expect them to accept compulsory military service as complacently as the Germans do. Active resistance would be as likely to follow one as the other. Political conditions are very different here from those which exist in Germany. The Americans are accustomed to do their own thinking, and are quick to resent every measure which seems to them to threaten their individual liberty. Without the support of public opinion no law can be enforced, for the citizen with his ballot makes short work of unpopular laws and lawmakers.

It is one thing to point out the difficulties that surround a subject and another to offer the means by which they may be overcome. It is easier to suggest some of the reasons why and how the public has become estranged from the sanitarians in this matter of vaccination than to propose a plan which will take in all the discordant elements, smooth away all animosities, and restore public confidence. It may be that a national board of health must be created to do this necessary work. A central organization, with authority to decide the vital questions which are now in dispute, to control the manufacture of biological products, to test their quality and regulate their sale, would exert an influence of incalculable benefit. Present evils must be remedied, and sanitarians will welcome any plan that promises to increase their usefulness and, by uniting their energies, enables them to move forward with unbroken front to do battle for the cause of science and the welfare of the people.

THE HYGIENE OF PREGNANCY.

By FREDERICK W. SMITH, M.D.,
SYRACUSE, N. Y.

HEALTH OFFICER CITY OF SYRACUSE; PHYSICIAN TO HOUSE OF PROVIDENCE; MEMBER ONONDAGA COUNTY MEDICAL SOCIETY, SYRACUSE ACADEMY OF MEDICINE, AMERICAN PUBLIC HEALTH ASSOCIATION; FORMERLY MEMBER NEW YORK STATE BOARD OF HEALTH.

Coincident with the advancement and perfection of the obstetric art, and the treatment of anomalous or diseased conditions of pregnancy, or the puerperium, there has not, it seems to me, been sufficient attention given to the essentially normal pregnant woman, having in view her physical comfort and peace of mind during the entire period of gestation, as well as a safe delivery at the end of that period.

It too frequently happens that the physician's attention to the pregnant woman is restricted to the actual period of labor. This I well know is not always the fault of the physician, but it has been too often such. While it is certain that pregnancy is a normal function in a healthy and vigorous woman, and not in any degree a morbid state, it must be admitted that a large proportion of the pregnant women of to-day are not, strictly speaking, in a physiologically healthy condition before the beginning of pregnancy; therefore, after making due allowance for the fact that this should be a perfectly healthy state, we must, I think, admit that a majority of pregnant women coming to our attention require professional advice, if not medical treatment.

A first essential for normal and favorable pregnancy is physical fitness. This implies more than a normal development and healthy performance of all functions on the part of both prospective parents; their personal and family physical developments should not be disproportionate. Parentage on the part of either man or woman suffering from certain diseases or degenerative tendencies is always deplorable; may even be little less than criminal. I almost feel like advocating it as a subject for legislative enactment. In the further consideration of my subject, I will mention three general factors that influence favorably the period of pregnancy and its final termination. They are hygiene, psychical, and medical.

The hygiene of pregnancy must begin in the childhood of woman, where only the foundation of a vigorous constitution, and a normal development can be attained by proper food, clothing, exercise, etc.; details and necessities of which are now well understood by most intelligent people, but most sadly neglected in the rearing of young women.

It is not uncommonly remarked by the passing generation of women that the child-bearing women of the present time are having troubles unknown to their mothers, or, in other words, the child-bearing powers of women are degenerating, and they wonder why their daughters are not as vigorous as were their mothers.

Such factors as the comforts, requirements, and indolent tendencies of modern civilization, unsanitary environment, occupation, etc., are, of course, each responsible for a share of trouble. It is certain that trouble in many instances during pregnancy or parturition arises from neglect in some essential particular or period during the physical development of women.

It is essential that women be taught an early and better understanding of themselves, of the physiology of the functions of ovulation and gestation, a better appreciation of the advantages of a vigorous physique, and the methods of attaining it under adverse circumstances.

Providence has ordained that child-bearing should cease before the beginning of retrograding changes, and the wisdom of this provision is obvious, inasmuch as the mother plays the stronger part in fœtal development, and maternal characteristics, physical and psychical, are more frequently and positively transmitted. Some will doubtless take exception to the latter statement; it nevertheless coincides with my observations. Undoubtedly the most favorable time for child-bearing is early in the child-bearing period after full physical and mental development has been attained. The state of pregnancy is not noted for improving the condition of unhealthy women; neither does it confer immunity from diseases to which non-pregnant women are liable; in fact, I think the general statement that disease tendencies are augmented or accelerated by that function is fully warranted. It is admitted that exceptions ocasionally occur.

Beginning with the onset of pregnancy, there occur such various alterations of strucure and functions as to require a hygienic régime peculiar to that condition which must be rational, and varied according to individual temperament, environment, former habits, and physical peculiarities.

Special topics to be mentioned in the discussion of the hygiene of pregnancy are: food, drink, clothing, bathing, exercise, rest, and care of the breasts.

The diet of healthy women with no unfavorable manifestations need not be very much varied from the ordinary. As a rule, meat should be eaten sparingly. Whenever a deficient elimination of urea is found or albuminuria exists, meat should be excluded from the diet, and a liberal amount of milk substituted in its stead.

All cereals, fresh vegetables and fruit, milk, and olive oil can always be taken in abundance. Whole wheat bread should form a portion of the diet of all healthy women. Candies and sweets generally should be avoided. The diet should be so selected, if possible, as to induce without other aid a daily evacuation of the bowels. Of greatest aid in this particular will be found the liberal use of apples and orange juice.

If morning or daily nausea or vomiting exists, meals must be light and taken four times daily, the last meal shortly before retiring at night. When the appetite is excessive, as it often is, it is well to stop eating a little short of full satisfaction.

Coffee and tea must be used in moderation; beer, wine, and other stimulants should be entirely prohibited. Water may and should always be taken in abundance. For the prevention of morning nausea or vomiting, a cup of warm water, to which has been added a pinch of salt, taken a half hour before rising, is worth more than all the drugs of the pharmacopœia.

Regarding clothing, the principle thing to bear in mind out of ordinary is to so dress as to avoid undue compression of the abdomen. This can only be perfectly done by suspending garments from the shoulders. Woolen underwear should always be worn during the entire period. Many women complain of weakness in the back or of lack of support on leaving off their corsets. Corsets may be loosely worn with safety and comfort until the end of the fourth month. After that period abdominal supports or belts, properly gored and made with back and side stays similar to the corset, will be found of advantage to those accustomed to tight lacing, or having pendulous abdomens.

In the observance of the hygiene of pregnancy there is nothing of greater importance than a plentiful amount of exercise taken daily and systematically. Women in moderate or impecunious circumstances usually find sufficient exercise in their household duties, but do not go enough into the open air. For women not obliged or inclined to do household duties a strict régime of daily exercise should be observed. Of all methods of exercise advocated or devised for the pregnant woman there is none so valuable as walking. Exercise is essential for proper muscular development; it materially favors assimilation and elimination, and the proper performance of all functions.

The pregnant woman, undoubtedly, should have more rest and sleep than is necessary in the non-pregnant state. A half hour's rest in the recumbent position after eating favors digestion and tends to prevent nausea.

Frequent bathing promotes functional activity of the skin and the general well-being. A tepid bath should be taken at least twice each week. Robust women can, with advantage, take a daily sponge bath. Those who cannot stand the daily sponge bath should indulge in a liberal daily use of the flesh brush. Sitz baths and douches should, as a rule, be avoided.

An important matter never to be neglected is attention to the breasts. After pregnancy has advanced to the fifth month the nipples should be bathed frequently with a solution of boric acid, fluid extract of quercus alba and glycerin, and the breasts covered with a pad of sterile gauze or cotton. Undue pressure or manipulation of the nipples must be avoided. By these simple methods fissure of the nipples and mastitis can almost surely be prevented. It is well-known that certain bacteria may find their way to the mammary gland through the normal milk ducts, and that mastitis may be due to glandular infection through a local lesion of the nipple, hence the necessity of its careful aseptic toilet.

It is no doubt a matter of considerable speculation as to how far psychological factors influence, favorable or otherwise, the pregnant woman or the fœtus in utero, but I think we must recognize that such factors have a considerable degree of importance, and give them our serious consideration.

Owing to the varying temperaments and susceptibilities, the physical and psychical peculiarities of women, their varied environment and conditions of life, pregnancy and the anticipations of prospective motherhood, produced a wide difference in the condition of individual minds. Emotional susceptibilities are almost always increased, and mental impressions are more pronounced; for this reason the pregnant woman deserves the most considerate attention on the part of friends and associates. Some women can and should attend church and places of public amusement and recreation, while it is best for others to keep in comparative retirement or in the companionship of considerate friends. Profound mental impressions or nervous shock may unquestionably produce structural changes in the ovum, and from such influences the pregnant woman should be protected to the utmost possibility.

After a healthy woman has conceived there is nothing so conducive to her future well-being as to be satisfied with her condition, coupled with a determination to do her utmost to bring to its fullest possibilities the new life just beginning. Unfortunately, this proposition is too frequently reversed, with results either fatal to one or both lives, or disastrous to the health of the unhappy survivor.

Every pregnant woman should, early in her pregnancy, consult her physician for thorough general physical examination. After this examination the physician should inquire into the mental state of his patient, her environment and condition of life, inherited or acquired peculiarities, endeavor to dispel the popular illusions that so frequently and needlessly cause anxiety and distress, and then to regulate her habits and daily life according to her conditions and necessities.

It is not then best to take for granted that pregnancy is advancing favorably, but frequent subsequent examinations should be made for the determination of irregularities of position, or placenta prævia.

Pregnant women are subject to disorders which may be traced directly to their new conditions, or to a deviation from the normal in structure or function existing prior to the inception of pregnancy, and which may have been so insignificant as to have been unrecognized before that time, and which only needed the added stimulus, or depressing influence of the new function to bring them into prominence. Disturbances directly due to the existence of pregnancy are most frequently the result of mechanical influences, or pressure, nervous reflexes, and nutritive changes. Without discussing theories as to causation of disturbances from pressure it is sufficient to say that the pressure of the gravid uterus frequently interferes with the functions of the bladder, kidneys, and bowels, also with the circulation, and sometimes with respiration.

For the relief of disturbances due to pressure there is nothing of more avail than systematic exercise and assuming of such positions or postures as will relieve pressure on the parts affected. Assuming the so-called knee-chest position several times daily will often give much relief and favor return circulation. Assuming the recumbent position, with limbs and hips elevated several times daily, is also advantageous. Women in advanced pregnancy should not attempt to sleep while lying on the back.

Nervous reflexes are various, the more common and noteworthy being nausea and vomiting. This reflex seems more common in women of nervous temperaments and in first pregnancies. It is often, I believe, the result of pre-existing displacement, flexion, or ahdesion following inflammatory processes. Neuralgias are common, and are, I am sure, often due to lack of exercise and consequent deficient elimination.

As a rule, all neurotic tendencies are aggravated, and for their treatment properly applied hygienic and dietetic measures deserve foremost consideration. Medical treatment must be such as to aid digestion and promote elimination, and sufficiently sedative to relieve nervous irritability. For the relief of purely nervous symptoms I have found no drug equal to asafœtida.

Unquestionably, pregnancy is occasionally the exciting cause of nutritive changes, which may vary from an exaltation to a marked depression of normal nutritive functions, but when such changes are pronounced and unfavorable there will often be found a predisposing environment, condition of life, or inherent personality. Unfavorable, depressed, or anæmic conditions call for an improvement of the quality of the blood by a nutritious and easily-assimilated diet, and the promotion of elimination. Iron and other tonics may be indicated. Cases of seeming exalted nutrition or plethora require a carefully restricted diet, a strict régime of exercise, and careful attention to excretory processes.

There has been a quite common notion even among an intelligent laity, that the use of certain decoctions or empirical medicines during pregnancy would influence, in a sort of general way, its course and termination. A safe procedure in the pregnant condition is to take no drug or medicine except for a specific purpose, and on the advice of a physician.

The greatest danger to which pregnant women are liable is from deficient urinary excretion. This danger seems greatest to women in their first pregnancies, and to women inclined to corpulency. Trouble from this source can almost universally be avoided by systematically observing the amount of urine voided each twenty-four hours and requiring its frequent and careful quantitative analysis for urea. The daily amount of this poisonous excrementitious element eliminated by the kidneys indicates more certainly than anything else the danger or safety of the pregnant women from eclampsia. For the approximate estimation of urea, the methods of Squibb or Doremus are sufficiently accurate and easy of manipulation. There has been in the past a common and erroneus idea that no serious renal or urinary disorder was liable to exist in pregnancy without albuminuria or nephritis. It must be borne in mind that deficient excretion of urea is not necessarily the result of nephritis, and that it may exist independently of albuminuria or of structural renal disease. The normal daily amount of urea excreted by the kidneys in different individuals varies according to their size and weight, the quantity and quality of food, the amount of exercise taken, and the degree of activity of other excretory organs.

Purdy states that "the mean amount of urea excreted by adult healthy males is 512.4 grains," and that "the absolute quantity excreted by women is below the average of men." Close calculation gives the average excretion of urea as .015 to .35 gram, per hour for each kilogram of body weight. Therefore it will be seen that in estimating the individual minimum limit of safety there are many factors to be taken into consideration. In the urine of pregnant women I have seldom found the daily amount of uria exceeding 450 grains. In the urine of sixty pregnant women, where I have made several examinations in each case, I have found an average amount of about 400 grains, or about 40 grains less than the amount usually found in the non-pregnant woman. I have noted this circumstance so frequently that I have come to believe that pregnant women normally excrete less urea than the non-pregnant.

When a pregnant woman of average size and weight, and under normal conditions of life, is found to be excreting by the kidneys continuously less than 300 grains of urea daily, her condition demands active treatment and careful watching during the remaining portion of her pregnant condition. As a rule, treatment will be more hygienic and dietetic than medical. As exercise favors elimination, such patients should be required to walk as much as possible in the open air. I have had such women walk from three to five miles daily with the greatest benefit and no discomfort.

Massage and other well-known methods of indoor exercise are worthy adjuncts of treatment for those who cannot be made to walk. Healthful activity of the skin can be promoted by frequent bathing, and the free use of the dry brush. Inasmuch as meat eating entails the necessity for increased excretion of urea, it should be largely and, perhaps, wholly excluded from the diet. Milk should always be taken freely by these women. The more serious cases demand an exclusive milk diet. As increasing the bulk of urine by excessive drinking of water unquestionably promotes the elimination of urea, soft or distilled water should be consumed freely. Digestion should be maintained as perfect as possible, and a free daily action of the bowels not neglected. Non-irritating diuretic remedies may be used when hygienic and dietetic measures are inadequate. Iron and tonics may be needed to improve faulty nutrition. The subject is a large one for a short paper, and I have attempted to touch upon only a few of the more important points.

The Mission of Societies for the Prevention of Consumption in the Anti-Tuberculous Crusade.—S. A. Knopf considers that the educational work of societies for the prevention of tuberculosis should not be limited to the mere distribution of pamphlets, but that there should be frequent popular lectures and reunions where verbal lessons are taught and discussed. One of the greatest missions of such a society is the propaganda for the erection of sanatoria for the consumptive poor, and also for those of moderate means, both adults and scrofulous children. Another important factor in the combat of tuberculosis, particularly among the poor of a large city, is the establishment of tuberculous dispensaries. In France and Germany such special dispensaries, aided by diet kitchens, which are essential in order to carry on the dietetic treatment with the unfortunate consumptive poor, have already done a vast amount of good. A society for the prevention of consumption must make it one of its duties to work for the better housing of the poor. All children at school should have more out-door instruction and more physical culture than they have now. Alcoholism is a strong predisposing factor to tuberculosis, and the creation of tea and coffee-houses where warm non-alcoholic drinks, including bouillon are sold in winter, and cool ones in summer, is to be encouraged. Tuberculous families should be influenced to leave the crowded city and move to a smaller town or village if it be at all possible for them to do so. Every member of a society for the prevention of consumption must consider himself a worker and a missionary in a field as important as ever lay before anyone who went out to preach the gospel to the heathen.—*The Montreal Medical Journal.*

The Treatment of Ileus with Belladonna Preparations.—F. Honigmann, after a résumé of the published cases in which this form of treatment has been employed, comes to the conclusion that atropine has no decided advantages over opium and should be used only when the latter drug fails. Cases of intestinal strangulation or of incarcerated hernia are not suitable for atropine while in obturation or adynamia of the intestine good results sometimes follow. The general effect of the atropine is sedative; the possibility of its exciting peristalsis has not yet been demonstrated clinically. The quieting effect of the drug often appears after very small subcutaneous doses (1-100 to 1-60, or at the most 1-30 of a grain), but sometimes repeated administration is necessary. The initial dose of 1.12 grain, recommended by Batsch, should never be given, and the susceptibility of the patient must always be tested by small doses. Whenever the ordinary dosage is exceeded symptoms of poisoning of greater or less severity are apt to appear. This is especially so with people over fifty years old, with whom caution in the use of atropine is always necessary. If the atropine does not cause the subsidence of the obstruction, as evidenced by the passage of flatus and fecal matter, within the first two days, one should not be misled by the apparently general improvement that is often produced into deferring surgical intervention. Only when this is refused or is for some reason absolutely contraindicated should the atropine treatment be persisted in.—*Centralblatt für Grenzegebiete der Medizin und Chirurgie*

A Case of Chronic Polyarthritis.—Augustus A. Eshner reports a case of chronic multiple arthritis that does not seem to fit exactly into the description of any of the commonly observed forms of that disorder, although it presents most nearly the appearances and features of deforming arthritis. A woman of thirty-one years had tumefaction in varying degree of the metacarpophalangeal joints of all the fingers of each hand, yielding a sense of elastic fluctuation on the dorsal aspect. The intrinsic muscles of the hands were slightly wasted and the hands exhibited a tendency to ulnar deflection. There was also multinodular swelling of the posterior aspect of the olecrenon process of the left ulna, and a smooth swelling in each popliteal space and on the dorsal aspect of each wrist. There was further some enlargement of the metatarsophalangeal joints of the first and fifth toes of each foot, and restrained movements of the right ankle joint. The movements of the jaw were free. Station was steady. The knee-jerks were preserved. The pupils were equal, of good size, and they reacted to light. Sensibility was preserved, and the patient was able to distinguish heat and cold. The patient had never had an attack of rheumatism. The action of her heart was rhythmic, the sounds clear. The urine was free from albumin and sugar. She suffered from gastrointestinal derangement, occipital headache, pain in the right ovarian region at the menstrual period, chilliness, sweating, and undue readiness of fatigue.—*Medicine.*

The Injury to the Young Cells Caused by the Common Surgical Dressings.—Robert T. Morris says that absorbent cotton is perhaps the most injurious of the dressing materials that are placed near the wound. Absorbent gauze and gutta-percha tissue are harmful, and the various antiseptics used, while they may destroy pus, have also the power of destroying new epithelium and new connective tissue formations. Skilful neglect of wounds requires much experience. Lister's protective oil silk is one of the best dressings to lie next to the wound; an innocuous and valuable dressing for the wound surface can be made by pouring collodion upon glass and peeling it off in a thin film after evaporation of the volatile part. Silver foil is becoming popular as a protective dressing. A dressing presented by the author is known as the Cargile membrane, first suggested by Dr. Cargile of Arkansas for the purpose of preventing the formation of peritoneal adhesions. The material, described in a recent issue of the MEDICAL RECORD, is a very thin gold-beaters' skin, made from the peritoneum of the ox. It is pervious to moisture, and at the same time it does not entangle new cells. Its presence, as an animal membrane, seems particularly grateful to the tissues, and the author has not yet found a dressing that has been found so satisfactory as this material to lie next the wound. "Sulphite laps" is the best and cheapest absorbent dressing to be found, but as yet is not obtainable in the market. The combination of Cargile membrane and sulphite laps ought to become a popular one.—*Mobile Medical and Surgical Journal.*

Two Cases of Diabetes Insipidus Transformed into Diabetes Mellitus.—Luigi D'Amato reports two cases and raises the question whether the passing of the one affection into the other consists of a superimposing or of a mere succession of diseases. He inclines to think that in his patients the latter was the case. As to the reasons for the transformation, he reviews the experiments of Bernard and of Senator, founded on the fact that the centers of polyuria and glycosuria are situated very near each other in the fourth ventricle, but concludes that it is impossible as yet to assert that this circumstance plays any part in the consecutive production of the two diseases. Until further and more convincing experiments shall have been made, we must be contented with the mere statement that diabetes insipidus may be transformed into diabetes mellitus.—*La Riforma Medica.*

MILITARY HYGIENE.

THE paramount importance of military hygiene in relation to the operation of armies has again been emphasized by an official statement from the British War Office, to the effect that of the total of 21,042 deaths among the British troops during the Anglo-Boer war, down to May 30, 1902, 13,250 were due to disease, while but 7,792 soldiers were killed in action, or subsequently died of wounds so received. Everywhere the British were hampered by the sick and the transport required for their supply. For every man killed on the British side, nearly two died of disease, largely of a preventable nature—and this proportion, far from being unexpected, is, when compared with wars of the past, of an unusually favorable character. Thus, the French lost, in the Crimean war, in round numbers, 95,000 men, of whom but 20,000 died of wounds. During the operations of the French army in Mexico the mortality from gunshot and disease was in the proportion of 10 to 29. During the Civil War the Union forces lost 93,969 from wounds and 186,216 from disease, while it is said that of the losses in the Confederate forces but one-fourth were due to the casualties of battle. In the short Austro-Prussian war the Prussians lost 6,427 from disease and 4,450 at the hands of the enemy. In the Russo-Turkish war of 1878 the Russians lost 102,799 men, of whom 16,578 were killed by the enemy. During the war with Spain, during the five months of nominal hostilities, there were but 345 men of the United States forces killed by the enemy, while 2,565 succumbed to disease—a ratio of about seven to one. This proportion was brought about, however, by the very brief duration and trivial nature of the military operations, and the fact that only a small part of our troops came under fire. The statistics of the Germans in the Franco-Prussian war furnish the only exception to the general rule that in all great or protracted wars, armies lose in strength less from wounds and deaths incurred in action than from disease. Judging by the past, and considering the conditions encountered, the British medical officers have no reason to reproach themselves seriously for their sanitary showing during the war just closed. From all accounts, they have done all they were allowed to do under the circumstances by their superior officers. The large number of deaths, however, chiefly due to diseases of a preventable nature, is practical evidence of the existence of serious defect in the military system. This defect lies, apparently, not with the medical department but with the line officers' branch of the service. The business of the latter being to fight, they are rarely far-sighted enough to appreciate fully that to do this they must keep well, and that to keep well they must obey certain sanitary laws well understood by their medical staff. While the average line officer will admit, without fully appreciating the significance of his admission, that military efficiency is crippled to a much greater degree by disease than by battle, he will not, in practice, take a fraction of the precautions against attack by disease that he will require to be carried out in guarding against an enemy. He may dimly understand that a thousand cases of sickness in his own ranks are equal, in their influence on military operations, to a reinforcement to the enemy of twice that number of able-bodied men, yet he is rarely willing to delegate to his medical staff sufficient power to enforce the sanitary precautions necessary to keep his command at its maximum strength and efficiency. While such conditions exist, and they exist in all armies, approximation to ideal sanitary standards is impossible. Military organization requires that the functions of the sanitary officer be purely advisory, and that the dictum of the commanding officer must be paramount. This being the case, the greatest hope for improvement, in the future, in the sanitary condition of armies in the field lies in the thorough education of line officers in the principles of military hygiene, a subject of which, at present, they as a rule know nothing, and in which they take little interest. Such education would not only guard against the commission of the more gross sanitary errors, but by bringing the importance of the subject home in a practical way, it would render commanding officers more attentive to the recommendations of their surgeons, and alive to the military value of such recommendations being carried out in detail. As soon as military sanitation is generally understood to be the factor most directly influencing success or failure in military operations and strategy, making or marring campaigns, and in this way determining the political fate of nations, just so soon may marked improvement be looked for in the morbidity statistics of armies in the field. The point must be emphasized to line officers that Providence is on the side of the largest battalions, and that hygiene and sanitation are not medical matters simply, but, from their effect on the fighting strength, are of vast practical value and importance from the standpoint of the tactician and strategist. The greatest obstacle at present to a closer approximation of the ratio for disease and injury in time of war is found in a lack of appreciation of this fact, dependent upon lack of education in military hygiene by line officers.

THE X-RAYS IN THE TREATMENT OF CANCER AND OF SKIN DISEASES.

DR. CHARLES WARRENNE ALLEN read, at a meeting of the New York County Medical Association in May last, a paper upon radiotherapy in cancer and skin diseases. The subject matter of the paper was wholly based upon practical results obtained by this form of treatment by Dr. Allen, and he gave an account of the favorable effects produced by the

x-rays in the treatment of twenty-six cases of a cancerous nature.

The most interesting portion of the paper was that in which was detailed Dr. Allen's views as to the best manner of using the x-rays. He said: "In regard to the method of securing the proper electric excitation, my experience has been limited to the static machine and the induction coil. My preference till now has been for the static machine, as giving less trouble in producing the requisite excitation of the vacuum tube. Both have produced good results; both have produced dermatitis in my hands. The advantage of the static machine is the steady discharge secured and the facility with which it is put into operation, provided it is so situated that the street main can be tapped to supply the motor power. The advantage of the coil is its portability, enabling one to set it up in the patient's house, employing the electricity from the street main, or, where this is not available, from a storage battery.

In conclusion, the experience of the writer led him to declare: (1) That the method is one of decided value; (2) It is not without its disadvantages, and the injudicious or careless use of it may bring it into disrepute. It is not a method likely to supersede or do away with all previous methods, but it has its decided place of utility.

In the treatment of cancer focus-tube dermatitis should enter but little into the question, as its importance is far outweighed by the gravity of the disease to be eradicated. The method appears to be of utility in recurrent cancers. If it proves as valuable as present indications promise, there is no reason why it should not be applied to primary cancer

Rules for the radiotherapist, so that he may obey the great rule *non nocere*, would seem to include *festina lente*. Stop ray exposures at the first statement of the patient that he feels a burning or pricking in the skin. Do not pave the way to disappointment by promising yourself or your patient too much for this new method. I know of no contraindication to the employment of other forms of treatment coincidently. The most favorable time to treat cancer, by the ray or otherwise, is early. At this stage the majority of cancers can probably be cured. When it has passed beyond a certain stage, cancer does not differ from tuberculosis in its probable fatal issue.

The use and value of x-rays in some forms of cancer and in certain skin diseases has now been demonstrated repeatedly. The method has its limits of usefulness, however, and charlatans have naturally exploited its reputation and exaggerated its curative properties to their own advantage and to the hurt of those members of a confiding public who have been so unwise as to place faith in their representations.

Radiotherapy, as utilized in the manner described by Dr. Allen, is a valuable remedial agent, if not actually curative in its action. The fact, too, must be remembered that the method is yet in its infancy, and the reasonable expectation may be found that in future more striking results will be obtained from its use than have been obtained in the past.

THE AERIAL CONVEYANCE OF SMALLPOX.

Dr. McVail in 1894, referring to the question as to whether smallpox could be conveyed by means of the air, said, "Summing up the evidence, as far as it is possible to sum up on a subject about which so much is still to be learned, we seem to reach the general conclusion that, as a result of the simultaneous action of causes favorable to the spread of infection, the contagium of smallpox may be conveyed atmospherically to a distance much greater than had been usually admitted—a distance measurable by quarters of miles." He added: "The practical conclusion of this whole question may be said to have been already arrived at. Smallpox hospitals are not now erected in the midst of towns, and those already in existence are being more and more sparingly used. Indeed, when the power of aerial convection is still doubted, it seems to be assumed that the prevention of personal communication is impracticable, and that accidents incident to the system of hospital treatment of smallpox within populous districts must be accepted as inevitable; so that the only remedy under the one theory, as under the other, is the removal of such institutions to a distance from populous places."

Dr. John C. Thresh, Lecturer on Public Health, London Hospital Medical College, writing in the *Medical Magazine* for June, differs from Dr. McVail in thinking that a practical conclusion has been arrived at, and says: "It is probably not sufficient to place such institutions at a distance from populous places. It may be necessary to avoid having large institutions, with consequent large concentration of patients and, therefore, of infective material, by substituting therefor a number of smaller hospitals, or a number of tent encampments, in which this concentration of infection cannot occur, or to such an extent only as to reduce the danger of the dissemination of the disease to a minimum. Smallpox hospitals do not necessarily cause widespread prevalence amongst the population around; on the other hand, they may spread the disease over a greater area than is generally conceived. Dr. Thresh then gives several examples coming within his ken in support of these views."

If this be indeed so, it would be advisable to ponder well ere spending the money appropriated for the purpose of providing New York with isolation hospitals for contagious diseases. There seems to be much reason in Dr. Thresh's view that here is less danger of spreading contagion when small hospitals or tent encampments are used than when all those suffering from this type of disease are massed together in one large building.

THE CASUALTIES IN SOUTH AFRICA.

Now that the Boer war is over, a short consideration of the casualties among the British forces will be instructive. In the first instance, it may be said that the losses on the British side have been much less than it was at one time supposed that they would total.

An actuarial correspondent to the London *Times* writes in that journal for June 16, as follows:

In two years, seven months and twenty days of war, down to the end of May last, 723 officers were killed or died of wounds or accidents, and 344 officers died from disease. In the same period the losses among the non-commissioned officers and men were: killed or died of wounds or accidents, 7,862; died of disease, 13,008.

To begin with the officers, the following table gives rates of mortality per 1,000 per annum from battle and disease during the first, second and third years of the South African war:

Officers—Rates per 1,000 per annum.

	1889 to 1900.	1900 to 1901.	1901 to 1902.
Killed or died of wounds.......	71.48	21.94	32.63
Deaths from disease...........	29.09	15.03	16.40
Total....................	100.57	36.97	49.03

There has been a noticeable advance in the losses among officers in battle during the past few months as compared with 1900–01, but the disease rate has remained much the same. The activity which the military authorities have shown in their efforts to finish the campaign during the South African summer accounts, no doubt, for the heavier death rate.

The following table shows that the non-commissioned officers and men have been more fortunate than their leaders:

Non-commissioned Officers and Men—Rates per 1,000 per annum.

	1899 to 1900.	1900 to 1901.	1901 to 1902.
Killed or died of wounds	19.62	10.87	11.13
Deaths from disease...........	31.07	20.56	18.24
Total....................	50.69	31.43	29.37

It will be observed that, while the men have suffered far less in battle of late than have the officers, they have been rather more subject to disease. The disease rates of both officers and men are, however, remarkably low, especially when it is remembered that the ordinary rate of mortality of British troops on foreign service is 15 per 1,000. During the last eight months in South Africa but few more officers and men have died of disease than would have died if no war had been going on at all.

With the exception of the first year's fighting in South Africa, when the losses both from battle and from disease were very heavy, the casualities in the latest war compare favorably with those of the most recent campaigns for which trustworthy figures are obtainable. In the last year of the American Civil war the total death rate of officers and men was reduced to 46.49 per 1,000, and in the Franco-Prussian war the total death rate was 46 per 1,000. In South Africa, during the closing months of the Boer war, the total mortality has been at the rate of 30.03 per 1,000. These figures will show to how great an extent war tends to become less deadly under modern conditions.

Uniform of Medical Department of Army.

It is understood that a board of officers, which is now engaged in revising the uniform of the army, has changed the insignia of the Medical Department and Hospital Corps from the cross to the caduceus. This device is not only very sightly, but is also particularly appropriate for the medical service of the army, the rod signifying power, the serpents healing, and the wings diligence and celerity. The matter of uniformity also was given consideration by the board, since in nearly every foreign army the caduceus is used as the insignia of the Medical Department. A further reason for the abandonment of the present cross is that this device is used by various relief organizations not under military control, and that this fact caused much confusion in the popular mind as to the identity of the Army Medical Department and Hospital Corps, during and since the war with Spain.

The board also proposes to change the distinctive color of the Medical Department from green to magenta. This is also in conformance with the customs of foreign armies, superificial examination showing that dark red, magenta or maroon is the distinctive color not only of the Medical Department of our own Navy, but also those of thirteen of the most important armies of the world, including those of England, France, Germany, Austria, Russia, etc. The attractiveness of the uniform of the medical service is much improved by the change, as the combination of blue and magenta is very rich and sightly, while that of blue and green is quite the reverse. In its general consideration of the uniform as a whole, particularly with regard to the uniform of the soldier for field service, the board is making many changes in the direction of comfort, hygienic advantage, and practical utility under the conditions of modern warfare.

Saving of Life in the Philippines.

War is not always hell, at least in its results. The number of lives saved in Cuba and Porto Rico by the sanitary measures which the result of the Spanish war empowered us to institute is already almost incalculable, but some notion of it may be gained by comparing the death rate of Havana or of Santiago de Cuba now with what it was before the American occupation. The saving in the Philippines is less apparent, because of the distance of the islands and because all the outcry has been of killings and of torture, but it is none the less real. General Lloyd Wheaton, who recently returned after being three years and a half in Luzon, is quoted as saying that "the devastations of war have cost many lives and the loss among the natives has no doubt been large, but when one takes into consideration the hundreds of thousands of lives that have been saved by reason of the sanitary precautions of the American Army and Civil Commission, that loss by war seems infinitesimal." Smallpox, he says, became epidemic soon after our troops entered Manila, and would have caused frightful mortality among the natives but for compulsory vaccination. Later, when bubonic plague appeared, the army medical men stamped it out energetically. Now cholera is there, but it is being gotten well under control and is claiming only a small proportion of the victims it would have had under the former unsanitary régime. "These three dangers," General Wheaton says, "have been met and overcome by the Americans, and it is perhaps no exaggeration to say that half a million lives have been saved by the presence of the Americans in the Philippines."

Gift for Public Baths for New York.

The recent agitation for more ample bathing facilities for New York City is fully justified by the circumstances of the case. American cities have exhibited a surprising indifference to the public bath question, both from its sanitary and moral point of view, and had it not been for the untiring efforts of a small but earnest band of social reformers the situation would have been worse than it is at present.

Even now the municipal authorities of New York City have shown no intelligent generosity in their contributions to provide public city baths. By no stretch of the imagination can $325,000 be considered a munificent sum to supply the teeming population of the second city of the world with adequate opportunities to practice the gospel of cleanliness. When the fact, too, is taken into consideration that a very large number of the inhabitants of New York consist of the poorest and, consequently, the dirtiest of the peoples of Europe, then the importance of inculcating into the minds of these persons the need of decency, and cleanliness must be obvious to everyone.

At any rate Mrs. A. A. Anderson has become impressed with this aspect of the case and has presented a site, on which, by funds provided by her, will be built a large model bath-house for the poor. The building, when finished, will be presented to the Society for Improving the Condition of the Poor and will be modelled after those which the city itself is about to build.

Newsboys and How They Live.

The most prominent feature of life in the United States is the desire, often inordinate, to make money. The love of money pervades all classes from the highest to the lowest. To the rich the old Latin proverb applies more closely than when it was written, "Crescit amor nummi quantum pecunia ipsa crescit," while the poor are imbued with a like spirit of gain.

One of the most distressing forms which this commercial instinct takes in America, is the precocious rapacity of the young. As soon as a boy can walk he endeavors to earn money. Newspaper selling is naturally one of the favorite modes to which resort is had to reach this end, for the reason that it is fairly easy, requires no capital, and is supposed to yield good profits.

In *Charities* of June 7 Mr. Everett W. Goodhue, writing of Boston newsboys, says that, as a rule, boys who sell papers on the street are schoolboys; that is to say, almost all of them are under fourteen and have homes. "There are, perhaps, two important facts which have been instrumental in placing the business in the hands of school boys: (1) The State compels all children under fourteen to attend some accredited school for a definite number of weeks each year, enforcing this through its truant system; (2) As waifs and strays have largely been looked after by various child-saving societies, this class of children has been removed from the streets. The bad effects of newspaper selling by schoolboys are these: it is a check to their school work; schoolmasters complain that the morning brings boys to school tired out and altogether unfitted for work. In answer to a question very recently sent out under the signature of the superintendent of schools in Boston nearly all the schoolmasters united in saying that, from their point of view, the most harmful feature of the business lay in the early morning selling, and the consequent ineffectiveness which it entailed upon the school work. Besides the common dangers which come from a close intimacy with the street and its life, newspaper-selling brings to the boy certain special dangers of its own. A boy with papers to sell has free access to places which should be interdicted to the young, and he is brought into contact with much that is vicious and immoral. The temptation to gamble and the craving for the cheap play are of these special dangers the most obvious and insistent. The Jewish lads, who constitute a great part of the young news vendors, are inveterate gamblers; the love of speculation appears to be in their blood, and this demoralizing influence has spread widely among the ranks of newsboys of all nationalities."

In order to combat the evils which are necessarily associated with the pursuit of news-vending, Mr. Goodhue says that in Boston some of the older boys have formed themselves into a union with the object of protecting the interests of the industry. The idea of this federation is to shut out the small boy from the business by raising the age limit to fourteen years, and thereby to do away with the excessive competition. The law of Boston would, if enforced, meet the exigencies of the case, for under it the small boy would be protected from many of the dangers of newspaper selling.

This licensing law, although not so effective as it should be, owing to the laxity of the city authorities in enforcing it, is nevertheless a useful one, as it keeps the very small boys and girls off the crowded thoroughfares, and away from those corners, where, especially at night, evil works in its worst forms. The mere fact that 3,500 boys in Boston take out licenses is a testimony to the usefulness of the measure.

Every large city might—with great advantage to the whole community and especially to those directly concerned—pass regulations prohibiting the sale of newspapers except by those fitted to undertake the work. It is much better in all ways that children should not be allowed to employ themselves in this manner. Up to the age of fourteen years a boy gets far more good in stocking his brain with useful knowledge than in learning the vices of the streets, although at the same time he may be acquiring a keenness in trading which in after life he can utilize in overreaching his fellowmen.

Tuberculosis of the Intestine.

At the Swiss Medical Congress held at Berne, May 30 and 31, Professor Kocher spoke on the above subject. There were about eighty cases on record. Professor Kocher reported about twenty-nine cases, in twenty-one of which he operated. The fact that primary tuberculosis was so rare spoke in favor of the thesis that Koch supported at the British Congress on Tuberculosis, that the disease was not transmittable from animals and that bovine and human tuberculosis were two different diseases. Secondary tuberculosis was very general; 500 out of Fenwick's 863 cases of consumption had some tuberculous lesions in the intestines. Professor Kocher wished to call his cases localized tuberculosis of the intestines, yet the previous history of the patients was generally doubtful as to freedom from tuberculosis, for they came from a tuberculous stock or had suffered from lengthy bronchitis or even pleurisy, or in infancy from glandular swellings; thus there was a possibility or probability of there being some primary latent tuberculous focus somewhere. In cases of constipation, infection of a slight lesion with tubercle bacilli was possible; generally the ulcers were localized in the cæcum. Ulcerations were followed by stenosis, the multiplicity of the ulcerations excluding the diagnosis of carcinomatous ulceration. For the diagnosis the diazo-reaction was of importance; the symptoms might be very slight; only localized recurrent pain might assist the physician who should do all he could to get the patient into the surgeon's care in the first ulcerative stage where excision could still be performed. Generally the surgeon only saw the patient in the second stenotic stage, suffering from all the symptoms of the chronic form of ileus with intermittent symptoms.

News of the Week.

The Vaccination Law Sustained. A man living in Queens Borough recently applied to the Supreme Court for a mandamus to compel the Board of Education of Queens to admit his son into a public school without requiring him to be vaccinated. The justice in denying the writ said that the State law excluding children from the common schools until they are vaccinated is a health law within the power of the Legislature to pass, and was therefore constitutional and valid.

An Apparent Increase in New York City Death Rate.—The Report of the Registrar of Vital Statistics of the Department of Health for the three months ending June 30 has recently been published. In the three months there were 17,173 deaths in the five boroughs, against 16,615 deaths in the corresponding period last year, an increase of 558 deaths. The increase in the death rate was due to the death of children under five years of age. The report shows an increase in the number of deaths from tuberculosis and a decrease in the number from diphtheria and cancer.

Civil-Service Examinations will be held in the usual places in New York State on July 26, of candidates for the following medical appointments: Assistant in Physiological Chemistry, Pathological Institute, salary, $700; Physician, third grade, regular school, for the State Hospitals, salary, $900 and maintenance; and the same, Homœopathic school, at the same salary.

Dismissal of a Civil-Service Examiner.—One of the medical examiners for the Municipal Civil-Service Commission was dismissed from the service recently on charges preferred by direction of the president, Col. Willis L. Ogden. The charges against him included six specifications, but his dismissal was based upon only four of them. He was accused of examining applicants for positions before they appeared before him in his official capacity, charging a fee for such examination; with improperly conducting the medical examinations; with having treated candidates in a discourteous manner, and so bringing the service into disrepute and occasioning many complaints and appeals from his decision; and, lastly, with rejecting certain candidates without examination, intending to give them further opportunity for preparation.

An Alaska Quarantine Station.—On account of the prevalence of smallpox at Nome, Alaska, and the danger of an epidemic under the rather crowded and unsanitary conditions prevailing in the mining camp, the Government proposes to establish a marine hospital and detention camp at some distance from the town. The Secretary of the Treasury has asked the Interior Department to transfer the jurisdiction of Sledge Island, an island near Nome, from the Interior to the Treasury Department, for use as a quarantine station for smallpox patients. There is already a marine hospital station on the island, and as soon as jurisdiction is transferred temporary pavilions for smallpox cases will be erected.

Typhoid Fever at Chickamauga.—Typhoid fever has again made its appearance at Camp Thomas, Chickamauga Park, Georgia, the first time since the epidemic among the soldiers during the Spanish-American War. The Surgeon-General of the Army has directed an investigation into the causes of the outbreak to be undertaken by Major Jefferson R. Kean, surgeon, and Dr. James Carroll, acting-assistant surgeon.

Dr. Jacques Loeb of the University of Chicago has been invited to go to San Francisco to take charge of the affiliated Colleges of Medicine and Dentistry of the University of California.

Dr. L. Emmett Holt of this city received the degree of LL.D. from the Syracuse University at the commencement on June 18. Dr. Holt was a graduate of the same college in the class of 1875.

A New Element.—Prof. W. Marckwald of the University of Berlin announces the discovery by him of a new radio-active element of great energy. It is separated from polonium, and resembles radium in the rays it emits, except that they are absorbed completely by paper. It exists in very minute proportions, combined with bismuth, in polonium.

Numerous Bequests to Charities.—By the will of Mrs. Mary J. Walker, who died on July 2, many charitable institutions in this city will receive bequests, amounting in the aggregate to half a million dollars. The following are the bequests: The New York Association for Improving the Condition of the Poor of the City of New York, $100,000, and an additional $50,000 to be devoted to the purposes of the Fresh Air Fund. St. Luke's Hospital, $100,000; also $25,000 to be used for indigent Christian females of the City of New York. Society of St. Johnland, of St. Johnland, Long Island, $50,000. Home for Incurables, Fordham, $25,000. Children's Aid Society of the City of New York, $25,000. Orphans' Home and Asylum of the Protestant Episcopal Church of the City of New York, $25,000. The Colored Home and Hospital, $25,000. Home for Old Men and Aged Couples of the City of New York, $25,000. New York Institution for the Blind of the City of New York, $25,000. New York Society for the Relief of the Ruptured and Crippled of the City of New York, $15,000. Samaritan Home for the Aged of the City of New York, $10,000.

The Casualties of the War of the Revolution continue, and each year adds its quota of thousands to the list of those injured and killed in consequence, if not in support of the Declaration of Independence, promulgated 126 years ago. The Chicago *Tribune* publishes annually a partial list of the casualties resulting from our barbarous method of celebrating the Fourth of July. This year, according to the figures collected by that paper, the injured were 2,649 and the killed thirty-one, and the loss of property by fire amounted to over a quarter of a million dollars. Over 500 persons were wounded or killed by bullets, and over 400 by premature powder explosions, while skyrockets were the cause of about one hundred casualties, and other fireworks, including firecrackers, of more than seven hundred.

The Smoke Nuisance.—New York is still suffering from the pall of smoke with which the burners of bituminous coal are enveloping it, but the nuisance is, perhaps, less than it was. The Health Department has done much to abate it, and would do more if the courts would punish the offenders. The Elevated Railroad in Manhattan has been forced to return to the burning of hard coal in its locomotives, and the Sugar Refining Company in Long Island City has been fined $500 for maintaining a nuisance in the burning of soft coal. There are still many offenders, but the number of convictions is growing, and we may hope this will have its effect as a warning to those still unpunished.

A Pioneer Discouraged.—Dr. Mary Conard, one of the women emergency physicians of the staff of the West Philadelphia Hospital for Women, has resigned because she was not allowed an escort when forced to go out on night calls. According to the rules of the hospital the emergency physicians have to go out on all calls, no matter what time of night they come in, and the lack of funds has prevented the appointment of a night watchman, who could act as an escort for any of the young women when summoned after dark.

The International Congress of Madrid.—Dr. J. H. Huddleston, Secretary of the American Committee, sends the following announcement: The Fourteenth International Congress of Medicine will be held in Madrid, Spain, from April 23d to 30th, 1903, under the patronage of their Majesties, the King of Spain and the Queen Mother. The President of the Congress is Professor Julian Calleja y Sanchez, the General Secretary is Dr. Angel Fernández-Caro, and the General Treasurer is Professor José Gómez Ocaña. The preliminary statement of regulations and program has just been issued, and it announces that members of the Congress will be physicians, pharmacists, dentists, veterinary surgeons, and other persons working at branches of medical science, both Spaniards and foreigners, who have entered their names and paid their subscriptions. Other persons who possess scientific or professional titles, and who wish to take part in the work of the Congress, may share in it under the above conditions. The subscription is thirty pesetas, and this sum must be paid, before the opening of the Congress, to the General Secretary, Faculty of Medicine, Madrid. A card of membership will be sent to the subscriber. Until March 20, 1903, subscriptions may be paid to the Secretary of the National Committee of the subscriber, but after that date subscriptions must be paid directly to the General Secretary at Madrid. Members will receive a summary of the proceedings of the Congress, and a full report of the work of the particular section which they join. The official languages of the Congress will be Spanish, French, English, German, and Italian. Papers must be sent to the General Secretary before January 1, 1903, to be certain of a place in the order of business. Papers presented later will be considered after the discussion of those regularly announced. Communications should be accompanied by a short abstract, which will be printed and distributed among the members of the Congress.

A Town without a Doctor.—The Secretary of the Avon Park, Fla., Board of Trade, writes that there is no physician resident in that town. The town is small during the summer, but receives a contingent of winter visitors, and the people who live in the "Flat Woods" around it would be glad of the services of a good physician in case of need. The place would be especially good for one who was interested in planting a citrus grove, or whose health made it necessary for him to seek a mild climate. Any inquiries may be addressed to Mr. E. M. Hyde, Secretary of the Board of Trade, Avon Park, De Soto Co., Fla.

State Board of Medical Examiners of New Jersey.—The annual meeting of the State Board of Medical Examiners of New Jersey was held at Newark, N. J., July 5, and licenses were granted to the candidates who successfully passed the State medical examination at Trenton, on June 17 and 18.

Forty-eight candidates were examined, and of this number forty were licensed, one was expelled, and seven failed to pass, making a rejection of 16.6 per cent. Twelve midwives were examined for a State license, five of whom were licensed and seven rejected, making a rejection of 58 per cent. Examinations were held in materia medica and therapeutics, obstetrics and gynecology, practice of medicine, surgery, anatomy, physiology, chemistry, histology, pathology and bacteriology, hygiene, and medical jurisprudence. Two hours were given to each section, in which ten questions were submitted. A total average of at least 75 per cent., or 675 points out of a possible 900, was required to obtain a State license. The policy of the Board in establishing and maintaining reciprocal relations with other States whose examining and licensing requirements are at least equal to those of New Jersey has met with the approval of the profession. The number of States which have entered into reciprocity of medical license with New Jersey is steadily increasing. The following officers were elected: *President*, Dr. John J. Baumann, Jersey City; *Secretary*, Dr. E. L. B. Godfrey Camden; *Treasurer*, Dr. A. Uebelacker, Morristown. The next examination will be held in September.

National Association of United States Pension Examining Surgeons.—An association with this title was organized in Saratoga during the annual session of the American Medical Association. A number of examining surgeons were present and several interesting papers were read. There are over four thousand pension examining surgeons in the country, and an effort will be made during the coming year to interest all of them in the new society. The officers elected for the ensuing year were: *President*, Wm. A. Howe, Phelps, N. Y.; *Vice-Presidents*, Wm. H. Hall, Saratoga Springs, N. Y.; Cyrus L. Stevens, Athens, Pa.; Charles James Fox, Willimantic, Conn.; G. Law, Greeley, Col.; *Secretary*, Wheelock Rider, Rochester, N. Y.; *Treasurer*, Charles H. Glidden, Little Falls, N. Y. All members of pension examining boards and all expert examiners are eligible for membership, and any such may become a member by sending his name and the dues for one year (one dollar) to the treasurer.

Consolidation of Denver Medical Schools.—A union has been effected of the Denver College of Medicine and the Gross Medical College, the new school being called the Denver and Gross College of Medicine, Medical Department of the University of Denver. The teaching force will embrace the faculty and instructors of both schools, under the management of a board of trustees, selected from each of the schools. The dean of the college is Dr. S. G. Bonney, the secretary, Dr. Robert Levy.

The Hackensack Hospital Training School.—At the commencement exercises of this school, held on June 30, a class of five was graduated. Dr. J. Leonard Corning of New York delivered the address to the graduating class, and Mr. George M. Fairchild, Jr., also delivered an address entitled "Some Advice from a Layman."

Obituary Notes.—Dr. JOHN NEWELL TILDEN died at his home in Peekskill, N. Y., July 10, at the age of sixty years. He was born at Onondaga, N. Y., and was educated at Hamilton College. He studied medicine at the Long Island College Hospital, from which he was graduated in 1862. He served for two years as surgeon in the Northern Army during the Civil War, and soon after the close of the war began practice in Peekskill. After practising for several years he became one of the managers of the Peekskill Military Academy.

Dr. GEORGE EDWARD TYLER died of pneumonia at Denver on July 7. He was a graduate of the Long Island College Hospital in the class of 1896. At the time of his death he was secretary of the Colorado State Board of Health.

Dr. J. C. BATTS of Norfolk, Va., was shot and instantly killed by a negro patient on July 10. The only explanation of the act was that the murderer who had been ill for some time was delirious. Dr. Batts was City Coronor.

Dr. Mary B. Damon of Minneapolis died in Weston, Mass., on July 6, from the result of a wound inflicted by herself during an attack of melancholia. She was born in Concord, Mass., about forty years ago, and was graduated from Vassar College in 1886 and from the Women's Medical College of the New York Infirmary in 1890. She practised medicine at Northampton, Mass., for six years, and then went to Minneapolis.

Progress of Medical Science.

The Boston Medical and Surgical Journal, July 10, 1902

The Basis for the Use of Alcohol in Therapeutics.—Arthur R. Cushny sums up his remarks by saying that alcohol deserves a place in therapeutics as a narcotic, and to a less extent as a stomachic, and in certain conditions as a food. He would not disguise the fact that it has drawbacks, like every other drug, but would plead that we must not allow ourselves to be guided entirely by consideration of any one of its properties, but must estimate in each case whether the sum total of its effects, good and evil, will benefit the condition.

The Nutritive Value of Alcohol.—Francis G. Benedict says that, from a review of the work done up to the present time, it can be seen that it would be manifestly unfair not to accord to alcohol a value as fuel and as a protector of body material—a value that may at times be of incalculable service to the physician, but considers that it would be equally unfair to deny that the latent tonic property of alcohol is such that in many, if not in the the majority of cases in which it is used as a food, such use is irrational. In health the multitude of other materials whose nutritive value is beyond dispute renders the use of alcohol as a food entirely unnecessary. In some pathological conditions, as in acute infectious diseases, the ease of absorption and high calorific value of alcohol probably more than counterbalance the toxic effects.

The Common Use of Alcohol as a Beverage.—Graham Lusk considers that the weight of evidence is in favor of the stimulation of the flow of the digestive juices by alcohol. If, however, too much alcohol be taken, there is too great an irritation to the mucous membrane of the stomach with decreased activity and resulting dyspepsia. Without doubt, alcohol reduces the power to do both physical and mental work. It reduces the power to learn. All the mental work done in experimentation quoted by the author was of the minute, painstaking sort. Dr. Woodworth has suggested that intellectual activity with some swing and freedom about it, and aiming only at broad effects, might be differently influenced, as seems, indeed, to be the case with some orators, musicians, and possibly writers. On the whole, the moderate use of alcohol as a beverage gives additional flavor to the food, and acts as a mild narcotic, often preceded by a period of exhilaration.

Journal of the American Medical Association, July 12, 1902.

Pruritus Ani; Strong Heat Its Best Remedy.—E. Andrews states that this form of therapy was suggested to him by the means employed by many wood-cutters and farmers to cure chilblains. The latter expose the bare skin to the direct heat of a fire, and find not only great relief but, after a few treatments, a permanent cure. Acting on this suggestion, Andrews has devised an apparatus consisting essentially of a rectal cylinder of hard rubber with a diameter of three-quarters of an inch, and passed two inches into the anus. The cylinder is closed at the upper end and has inlet and outlet connections. In this way it is possible to run a stream of hot water through it. The highest heat endurable is about 130°F. A thermometer in the supply bag will indicate the right temperature. The patient may lie on the side with the knees drawn up or sit obliquely on one hip or astride a chair with the hips over the edge. At first the injections may be taken twice daily; then at intervals of several days. Of course, the physician should remove all discoverable causes of the pruritus.

Electrothermic Hæmostasis in Abdominal and Pelvic Surgery.—W. J. Downes details his experience along the line indicated by the title of his paper and figures several instruments employed. His experience leads him to believe that there is less pain after abdominal operations with electrothermic hæmostasis than with the use of ligatures. In certain cases resulting fatally from various causes (not from the hæmostatic agent) he found evidence on post-mortem to indicate that adhesions are much less liable to occur than after ligature operations. The further fact that in a field capable of isolation the work within the abdomen can be quite bloodless is another reason in favor of this method of hæmostasis. Special reasons are advanced with reference to operations for cancer salpingectomy, ovariotomy and appendectomy. In the first, we can obtain not only hæmostasis, but we seal the lymphatics, in the second, we leave a sterile, non-patulous stump; in the third, we ensure the absence of secondary hæmorrhage, and in the fourth, we find electrothermic hæmostasis cleaner and bloodless, more sterile and, with proper technic, there can be no escape from the cæcal or distal end at the line of section. It will thus be possible to obtain an aseptic abdominal closure in all cases of unruptured appendicitis, even if the content of the appendix is pus, thus materially shortening the period of convalescence. The description of the apparatus employed must be read in the original paper.

Medical News, July 12, 1902.

Therapeutic Uses of the Organic Extracts.—O. T. Osborne first discusses thyroid extract. If there are cerebral excitement, palpitation, and progressive loss of weight, thyroid treatment is contraindicted; if the patient is sleepy, apathetic, with but little palpitation, has no headache, and is putting on weight, thyroid treatment will probably benefit the case. This drug is of value in amenorrhœa or scanty menstruation, as it produces a tendency to hemorrhages. Thyroid has been used by some clinicians in carcinoma of the uterus as well as carcinoma elsewhere. Personally, the writer has not seen any benefit from its use. He is inclined to think that it would be wise always to try thyroid treatment in the insanity of the menopause and in puerperal insanity, as there is probably a disturbance of the thyroid at these times. The writer knows of no established therapeutic use of the pituitary substance except in acromegaly. The toxic headache of acromegaly is always relieved by pituitary tablets. The exhibition of pituitary extract is a logical treatment for dwarfs. The writer has had good success in giving the thymus gland in cases of Graves' disease in which feeding of the thyroid gland aggravates all the symptoms. It is also beneficial in the treatment of tuberculosis. Adrenalin should be used in all cases of low vasomotor tension, typically in Addison's disease, and in the anæmias. It should be used with care in persons over fifty years of age. There is much discussion at present about the ovary, but little is known of the internal secretion of this gland. Until careful chemical investigations may reveal some isolated principle, the therapeutic efficiency of mammary extract will remain unsatisfactory.

Tendon Transplantation.—J. Hilton Watterman reviews the history of this subject and quotes the indications given by Vulpius for transplantation: The operation is impracticable only when all the muscles of the limb are paralyzed. If one muscle or group of muscles be still intact, we may think of the possibility of improving the functions of the limb by transplantation and of preventing or removing the secondary contractures or deformities. He shows schematically nine methods by which tendons may be anastomosed. The subject of diagnosis is of the greatest importance in regard to tendon transplantation. It is not justifiable to operate if the diagnosis is not certain. In the great majority of cases the operation of transplantation has been performed for paralytic equinovarus, due to infantile anterior poliomyelitis. In 1895 Goldthwait noticed that the sartorius generally escapes paralysis in those cases of anterior poliomyelitis which involved the thigh. He conceived the idea of making this muscle do the work of the paralyzed quadriceps. Before this all transplantation had been done with muscles having well-formed tendons. The lower extremity of the sartorius was attached to the quadriceps extensor just above the patella. Excellent results have been thus gained, and the flinging gait and rotation have been obviated. Opportunities for ideal grafting are not common, because the necessary proximity of sound and paralyzed muscles may not exist, but it is not indispensable that the two muscles be synergists, for one muscle may be made to do the work of an antagonist or of an indifferent muscle. For instance, an extensor tendon of the finger may be passed through the interosseous space and transplanted into a flexor tendon. In regard to the ultimate results, with especial reference to the wearing of braces, the writer thinks that we should seldom expect to secure by transfer of function alone complete equilibrium between antagonistic muscles. We must be content with a gradual strengthening of those portions of muscles which are compelled to perform new duties. The writer then carefully considers the details of the operation.

New York Medical Journal, July 12, 1902.

Electric Light in Diseases of the Respiratory Organs.—W. Freudenthal details his experience with this agent in tuberculosis and hay asthma. As to the former, he concludes that the electric light can be regarded only as an adjuvant to the host of other remedies at our disposal. At times it is of great assistance. In hay asthma he has applied the remedy to twenty-four patients. Out of these fourteen experienced decided improvement in all respects very soon after the treatment was commenced. In the other ten, results were not decisive. He applied the light directly to the face, letting the rays pass through a blue screen. He follows the same plan as to the chest if there is an indication for its application to this region.

Tetanus.—K. E. Kellogg makes a plea for the injection of carbolic acid in one-half-per-cent-watery solution in a circular manner around the wound. He says, in support of this mode of treatment, that actual figures indicate as many cures from the use of chemical agents as from antitoxin, though the use of phenol does not contraindicate the administration of antitoxin. There are no exact methods of measuring tetanic antitoxin, and inasmuch as the antitoxin is not a stable article, we are not justified in continually saturating the system (which would appear essential) with this agent, of which we know comparatively little. On the other hand, of carbolic acid we know considerable, and we have a definite and reliable method of ascertaining its action and the extent to which it should be used. Investigators have failed to save infected animals, even with the immense doses of the antitoxin. Cases have been treated alternately, first with the antitoxin and then with phenol, with the more satisfactory results during the administration of the latter.

Brief Notes on Mitral Insufficiency.—T. E. Satterthwaite gives a brief description of the disease based on personal clinical experience. He notes that up to the period of failing compensation the three cardinal signs are: (1) A systolic murmur at the apex conveyed to the left; (2) Accentuation of the second pulmonary sound; (3) Increased transverse dulness of the heart. In and after breaking compensation, the diagnosis must be based on the previous history, because the abnormal transverse dulness may be the only one of the three cardinal physical signs left from which to construct a diagnosis. If stenosis coexists, as it does in from 70 to 80 per cent. of the cases, we must expect a systolic thrill around about the apex in from 15 to 60 per cent. and a presystolic murmur in at least from 10 to 30 per cent. In children or young people there may be a bulging of the præcordia. He adds that in instances in which there are merely fresh vegetations on the valves sufficient to cause a very slight insufficiency, no murmur may exist. After all the condition is comparatively easy to determine because the valve is to the left and behind, and as the murmur follows the regurgitant current, which flows more or less backward as it goes upward, it is carried somewhat behind the angle of the scapula and may be heard also in the axilla. If it is heard in both these places, the diagnosis is pretty certain.

American Medicine, July 12, 1902.

The Efficacy of Recent Vaccination.—Wm. M. Welch presents striking evidence of the protective power of vaccination, especially of recent vaccination. He states that during the recent epidemic of smallpox in Philadelphia no person who had been recently successfully vaccinated, was admitted to the hospital with smallpox. He reports many instances of the prophylactic power of recent vaccination. One family of father, mother, and three children were admitted to the hospital. Both father and mother were suffering from varioloid. The oldest child, five years old, showed a good scar, the other two, one ten months and one three years old, were vaccinated a short time before, and presented two vaccine vesicles, that were developing perfectly. These three children remained in the hospital seventeen days under constant exposure without taking smallpox. During the past winter 170 students received instruction in the smallpox wards in the Municipal Hospital of Philadelphia, and not one of them contracted smallpox. In the present epidemic about 125 persons, physicians, nurses, ward maids, cooks, laundresses, etc., have been continuously exposed to the disease and not one has contracted it. All those employed in the smallpox pavilion, except two or three who had the disease at an early period of life, owe their immunity to vaccination.

A New Method of Bone Grafting.—A. W. Morton advocates the transplantation of bone from lower animals to repair bone defects in man. He reports a case, which he states is unquestionably the first successful instance of bone transplanting by vascular attachment from animals to man. The patient was a man of forty-five years. He had fallen and received a compound comminuted fracture of the right tibia and fibula. The fibula united, but the tibia did not. The end of this bone became necrotic, and five inches of the lower end was removed. Improvement followed, and a few days later the periosteum was resected back and the end of the bone was freshened, so there was free hemorrhage. A medium-sized dog was prepared, and the left fore leg amputated just above the tarsus. The ulna was left one inch longer than the radius; the skin and muscles were divided by a longitudinal incision for about four inches and left attached, except about three inches at the lowest end, which was removed to the periosteum. The cut ends of the ulna entered the cavity of the tibia one inch and were united with silver wire to same, the fibula was wired to the end of the tibia. The upper part of the incision in the patient's leg was closed by stitches; this placed the dog's leg nearly on the same plane as the man's leg; the wounds were drained; all the stronger tendons in each leg of the dog were cut by a subcutaneous incision. The other three legs of the dog were encased in plaster-of-Paris separately; the entire dog and the man's leg were encased in a plaster cast extending to the knee of the patient. The patient's condition gradually improved and his temperature and pulse remained about normal after the third day. Five weeks later the man was placed under medullary narcosis, and the dog under ether; the cast was removed, the skin and muscles were separated from the dog's leg, and the two bones were divided near the joint and placed in contact with the astragalus; the skin and deeper structures were united, except at the point of drainage, which slowly closed by granulation. The man now has a very useful leg.

Philadelphia Medical Journal, July 12, 1902.

Intestinal Anastomosis.—John R. Cook reports several cases of this nature. In one case of gunshot wound of the bowels, he removed twenty-eight inches of intestine in one place and two in another, putting in two Murphy buttons. In cutting away the gut he did not remove the V-shaped piece of mesentery, but simply cut enough of it to clear the gut, and with a long ligature tied it off in one continuous gathering mass, and when the gut was brought together, folded the mass of mesentery on itself and stitched the edges together to hasten union and prevent accident by loop of gut slipping through it. The patient entirely recovered. In another case of intestinal obstruction he removed twenty-one inches of the intestine. The patient was well in five weeks. He believes that the shock is lessened in not taking out the V-shaped piece of mesentery.

Some Points in the Treatment of Crushing Injuries Involving the Large Joints.—John Glendon Sheldon describes his method of treating these injuries: The injured tissues are cleaned as thoroughly as possible. After the detached fragments of bone have been either removed or placed in their proper positions, the joint cavity is completely closed by the suturing of ligaments or muscles. The defect in the skin is not closed. Skin incisions, made for the purpose of exposing deep structures, are sutured, but the traumatic wound is not repaired in any part. The reasons for this treatment are: (1) The skin and subcutaneous tissues are subjected to more trauma than are the deeper structures and more unclean material is brought in contact with and is ground into them; (2) Thus the vitality of the skin and underlying tissue is more reduced than is that of the deep tissues, and their cleansing is more difficult and less efficient than that of the deeper structures. Thus the clean-joint cavity is protected from the unclean superficial structures. The superficial tissues are thoroughly drained. Secondary infection of the joint cavity is impossible. The possible disadvantage of the method is that if the deep structures have not been rendered aseptic, secondary drainage becomes necessary. But an opening into the joint cavity can easily be made, and the objection is not serious.

The Lancet, July 5, 1902.

Cases of Gastrotomy for Recent Gastric Ulcer.—The histories of three cases are given in detail by C. W. Mansell Moulin. Two patients recovered and one died. In the first case section did not reveal any perforation of the stomach wall but an ulcer was found and excised. The patient recovered, having had a double parotitis during convalescence. In the second case a similar gastric condition was found and a similar operation performed. Parotitis set in, first on one side and then on the other. Suppuration followed and, though relief ensued when the abscess was opened, the patient died on the ninth day after operation. Autopsy revealed contracted kidneys. The third case was similar to the other two as to nature and operation. The author adds that, so far as hæmatemesis is concerned, it is clear that age and sex make a very material difference. A much greater risk may be run in the case of a woman under thirty years of age than in the case of those over thirty years of age, and especially in the case of men. If there is one single severe hæmorrhage in a case in which the previous history suggests the presence of a chronic gastric ulcer (when the bleeding is probably due to an opening in an artery of some size and is not merely capillary); if in any case there are two separate attacks of severe hæmatemesis at a short interval; or if there are frequent small hæmorrhages, so that the patient is becoming seriously anæmic, he believes that the risk of operation is very decidedly less than is the risk of leaving the patient alone, and that the best interests of the patient would be consulted by giving him or her the chance of operation before the condition becomes desperate.

A Few Observations on the Blood Pressure in Mental Disease.—H. de M. Alexander finds the blood pressure considerably increased in acute passive melancholia, less so in acute demonstrative melancholia, and generally low in chronic melancholia, increasing when the mental symptoms become more acute. In mania the pressure is above normal, though not so marked as in melancholia. General paralysis presents many types of insanity, and consequently the results of examination varied greatly. In the later demented stages the pressure readings were uniformly low. In pure senile mania and melancholia the readings obtained corresponded to those registered in the same affections occurring in an adult or an adolescent; but the blood pressure was, as a rule, much above normal in that variety of senile insanity which is associated with dementia and which is characterized clinically by a constant fidgety motor restlessness; and it is in this form of insanity that drugs of the nitrite class are of most benefit. The blood pressure in mania appears to be considerably modified by the presence of general physical debility, and thus restlessness in the chronic maniac of poor physique is, as a rule, associated with a normal or even low blood pressure, though an elevation may occur with any increase in excitement. Without the presence of any organic disease to account for it, some cases of senile dementia, with constant restlessness as a marked symptom, have a high blood pressure, and these patients are often much benefited by the administration of such a drug as erythrol tetranitrate. As is well known, an attack of mania is usually ushered in by certain premonitory symptoms and one of the commonest of these is mental depression. On the appearance of any of these premonitory symptoms it is often possible to ward off the acute attack by confining the patient to bed amidst quiet surroundings and by keeping him on a low diet—precisely as a case of melancholia may be treated. He has always found the symptoms, mental and physical, antecedent to an attack of mania to be accompanied by a rise in blood pressure.

Difficulties in the Diagnosis of Smallpox.—W. T. Freeman reports the case of a boy of ten years with a rash of a scarlatiniform type. There were the usual febrile symptoms, followed in due time by some peeling but no albuminuria. Ten days later he again became sick with high fever, and nodelike swellings appeared on the front of the tibia and over the forehead and left orbit. There was some swelling in and about the left knee-joint. When seen by the author about a week later, he had still a high temperature and the swellings referred to, were still in evidence, and he had developed additionally a profuse bullous rash; the vesicles or bulæ ran in size from that of a pin's head to near the diameter of a shilling-piece. The bullæ were principally grouped on the legs and buttocks, but some were also present on the arms and lower abdomen. Some of them had an umbilicated appearance and all were hæmorrhagic. They were commencing to dry up, but tests applied as carefully as possible practically proved them to be multilocular. The history of this second rash was that it first appeared as a papular one and subsequently became vesicular and bullous. There was a largish bulla on the left side of the tongue. The boy seemed to be very ill. He had all the appearances of a congenital syphilitic—typical upper incisors, flattened bridge of nose, scars at the angle of the mouth, etc. He had good vaccination marks, but had not been revaccinated. One week later he was much improved, the vesicles and bullæ were dried up into hæmorrhagic scabs, the swellings had nearly disappeared, and the temperature was normal. The patient recovered. The author was in doubt as to the nature of the case, thinking that he had perhaps to do with an anomalous case of variola in a partially protected but specifically unhealthy child. His later judgment, however, led him to the view that the condition was a developmental erythema, an erythema of the nodose type passing on through stages to a bullous type of rheumatic purpura. It is to be added that, as the boy improved, he was vaccinated and a full reaction followed.

The British Medical Journal, July 5, 1902.

The Epidemiology of Smallpox in the Nineteenth Century.—Arthur Newsholme concludes that the chief governing factor in epidemics of smallpox is personal infection; the disease spreads from town to town, and from one country to another, not always affecting different countries in the same year, as it might be expected to do when similar climatic conditions occur in the different countries if climatic conditions had a predominant influence. There is, however, some further factor responsible for the causation of the greater epidemics and pandemics of smallpox, which, for lack of a better term, we must still designate by the term of "epidemic constitution." As the expression of a fact, without being committed to a theory, we may admit with the older epidemiologists that there is a *constitutio epidemica variolosa* What is meant by this is that at certain irregular intervals smallpox, as judged by its wider spread, is more infectious than it is in other years with equal opportunities for its dissemination. There is no regular periodicity for these greater epidemics, but there is a fairly regular periodicity for the minor epidemics, which has become disturbed and the intervals protracted in well-vaccinated communities.

A Century of Vaccination: Smallpox Epidemics and Smallpox Mortality before and since Vaccination Came into Use.—E. J. Edwardes states that for nearly two decades after vaccination began in the nineteenth century smallpox epidemics appeared to be on the point of dying out everywhere. But toward the end of the second decade they began to recur with altered characters. They were not so extensive as before, and they attacked the vaccinated in increasing numbers as the years rolled by. Thus, finally the lesson was learned that protection decreases with time. At the time of the great pandemic of 1870 the average rates in four countries with compulsory vaccination—England, Scotland, Bavaria, and Sweden—were as follows: 361, 314, 346, and 333. The average rates in four countries without compulsory vaccination—Prussia, Austria, Belgium, and the Netherlands—were: 953, 1,360, 1,293, and 958. The latter countries show a mortality more than three times that of the first-named countries. As to the ages of those who died, where compulsory vaccination existed, the chief mortality was borne by the age class above twenty years, but where there was no compulsory vaccination the chief mortality was among children. The results of the revaccination law of 1874, in Germany, were the entire abolition of smallpox epidemics in that country. The rate is almost *nil*. The few deaths which occur are due, chiefly, to importation from Russia and Austria. The German Army had already enjoyed revaccination ever since 1834 with splendid results. But the new law at once made a great difference in the smallpox mortality of the army, for it abolished the mortality altogether. This proves that the protection which an individual acquires by vaccination and revaccination is greatly increased if he is surrounded by an equally protected community. Hence it is the right and duty of the State to insist on universal revaccination.

The Complications of Vaccination.—T. Colcott Fox declares that many of the variations in the development of the vaccine pocks are of comparatively little importance. The incubation period varies. The pocks may develop unequally. The "raspberry sore" is mentioned. This begins as a red elevation at the site of inoculation, quite similar to the papule of true vaccina, but instead of advancing to the vesicular stage, it remains hard, dense, bright red in color, and nodular, looking not unlike a small nævus. It remains, as a rule, for some time, but may be dissipated by a mercury and carbolic-acid plaster. With regard to an excessive degree of local inflammatory reaction, some excess may occur after the use of bovine lymph, and in revaccinations. There are also variations in the healing and formation of scars. Of the eruptions not peculiar to vaccination there is a group embracing all types, from the erythematous to bullous and hemorrhagic; and they may accompany local pocks. Various phases of urticaria are met with in the adult. In addition to the trifling miliaria and sudamina, some papular and vesicular eruptions are occasionally met with, as after the ingestion of drugs, somewhat difficult to classify, but usually of little significance. Purpura is of very rare occurrence. The very rare disseminated gangrenous lesions, the so-called vaccina gangrenosa is to be carefully distinguished from the local gangrene or necrosis which sometimes occurs at the points of inoculation. It is possible that impure lymph-containing organisms, such as staphylococci, or streptococci may contaminate the vaccine lesions from the start, and produce systemic poisoning with generalized rashes, or, perhaps, vesicopustular eruptions. Such results are generally due to improper methods of vaccination, or to secondary contamination of the points of inoculation. Tetanus is rare. Psoriasis, eczema, and strophulus may occur in close association with vaccination. Syphilis, tubercle, and leprosy may possibly be inoculated at the time of vaccination or by subsequent contamination. The event is extremely rare. Many of the bad results of vaccination are due to imperfect sterilization of the skin and want of protection against the invasion of foreign organisms.

Deutsche medicinische Wochenschrift, June 19, 1902.

Typhoid Bacilli in Urine.—Busing calls attention to the length of time that typhoid bacilli may be present in the urine following typhoid fever and the great danger of contamination therefrom. A case is reported in which the bacilli were found in the urine of a patient who had been convalescent from typhoid for four months. Much experience has shown that the administration of urotropin in these cases is promptly followed by a disappearance of the typhoid bacilli from the urine. It is always best to continue this drug for a week to ten days after the organisms have so disappeared.

Artificial Ripening of Cataracts by Förster's Method.—W. Stood reports 130 cases of cataract which were artificially ripened by massage according to Förster's method, and then enucleated. In 120 of these the cataract was thus matured, so that enucleation could be performed in from three to six weeks. In three infection took place and the treatment was necessarily discontinued. The end results and the final vision obtained fully equalled or exceeded those which follow operations upon cataracts which have been allowed to naturally ripen. Nuclear and lamellar cataracts, which occur in people over sixty-five years of age, are not suitable for this treatment, but in all other cases much time may be saved and satisfactory results obtained by its employment.

Angina Diphtheroides (Vincenti).—Lämmerhirt reports a case of this disease which is of interest on account of the unusual tonsillar lesion present. There was no membranous formation, but a sharply-defined, rapidly-growing ulcer presented itself on the left tonsil. Bacteriological examination showed the presence of the bacillus fusiformis, together with numerous spirilli. The constitutional symptoms were slight and lasted only about twenty-four hours. At the expiration of twenty days the ulcer had entirely healed. The treatment consisted of the local applications of a 3 per cent. solution of nitrate of silver, but it cannot be said that any material benefit was obtained thereby.

Berliner klinische Wochenschrift, June 23, 1902.

Virulence of Bacteria.—R. Pfeiffer and E. Friedberger, in an endeavor to elucidate this subject, have undertaken experimental studies with respect to the cholera spirillum. They conclude that the virulence or non-virulence of this organism depends upon the number or degree of affinity of its haptophore groups. In the virulent spirilli this number or degree of affinity is from five to ten times greater than in the avirulent. The degree of immunization produced by the inoculation of cholera spirilli is directly dependent upon the degree of virulence of the inoculated culture. The same holds true for typhoid and pest bacilli.

Complementophile Group of the Amboceptors.—P. Ehrlich and H. T. Marshall, as the result of recent researches, claim that the haptophore group of the amboceptor possesses a number of complementophile groups. These are divided into "dormant" and "non-dominant" groups, according as they show a greater or less attraction to the corresponding groups of the cell to which the amboceptor unites itself. In many cases all of the complementophile groups come into action at the same time, but in others the action of the dominant precedes that of the non-dominant group. In still other cases this is reversed. In all of these instances the specific action is that of the dominant complementophile group.

Münchener medicinische Wochenschrift, June 24, 1902.

Narcolepsy.—L. Loewenfeld reports a case of this interesting disease, which was first described by Gelineau in 1880. In general, the symptomatology was characterized by frequent and brief attacks of sleeping, together with a considerable restriction of the locomotor functions. The chief therapeutic measures were directed along the lines of hypnotic suggestion, and much benefit was derived therefrom. It seems probable that this condition is a disease sui generis, caused by a pathological alteration of the nervous system, which is to be regarded as a neurosis, since marked structural changes are evidently not present.

Röntgen Dermatitis.—Wiesner's patient was a man who had been employed for many months as a subject for the demonstration of the Röntgen apparatus. For eleven months no injurious consequence resulted therefrom. There then appeared on the hands and arms an eruption similar to a chronic dermatitis; this spread to the trunk and face. Suppuration occurred in many locations. The eruption lasted for several months, and did not seem to be influenced by any treatment, although the local use of orthoform relieved the subjective symptoms to a certain degree. The author agrees with Barthelemy in regarding the disease as trophoneurotic in character.

Sequelæ of Infantile Syphilis (Acquired and Hereditary).—Alfred Martin, as the result of statistical research, says that syphilis, if acquired under two years of age, reduces the resistance of the patient, so that the ordinary diseases of childhood are liable to run a very severe or fatal course. If acquired after this age, no such marked influence seems to be exerted. Syphilis hereditaria præcox is attended by a high mortality, since, of ten cases noted, in seven death took place under the age of one and a half years. In syphilis hereditari tarda the prognosis is much better, as of twenty-two cases six died at an average age of fourteen years. Syphilis acquired after two years of age, however, gives a more favorable prognosis than late hereditary syphilis. No special relation seems to exist between hereditary syphilis and the infectious diseases. No special predisposition to diseases of the nerves or vessels could be detected in subjects of infantile syphilis, either acquired or hereditary.

French and Italian Journals.

Fulminating Tropical Hæmaturia.—Marco Levi Bianchini reports the case of a man who had been four years in Africa and had not suffered from malarial fever. He was found to be profoundly anæmic, with a filiform, slow and weak pulse, and suffering from general weakness and lassitude. One evening he complained of slightly chilly sensations, and the next day had fever. Hæmaturia occurred, and in two days he died. The author considers the case to belong to the class described by Marchiafava as "pernicious hæmoglobinuria," or a post-malarial form of spent infection in which the parasites have disappeared. —*Annali di Medicina Navale*, May, 1902.

Actinomycosis.—Latarjet reports a case of this kind that had come under the care of Tixier. The patient was afflicted with actinomycosis of the face following on an injury by a hand-screw. The injury had been violent enough to form a hematoma, and after that had suppurated, yellow grains were found in the pus. These yellow grains were abundant and very characteristic. The diagnosis was established in an absolutely certain manner, but it was difficult to account for the manner of the infection. The patient could not remember seeing a cow with this affection, nor was he in the habit of munching bits of grain.—*Lyon Médical*, June 22, 1902.

Latent Hepatic Steatosis of Alcoholics.—A. Gilbert and P. Lereboullet declare that latent hepatic steatosis has an important place in the pathology of the liver. Its frequency, unsuspected on account of its latency, is considerable, since it is, without doubt, more common than all the varieties of cirrhosis resulting from the action of alcohol on the liver. Its importance depends upon the fact that it constitutes the hidden imperfection in young subjects that makes the prognosis bad of maladies apparently benign. For example, pneumonia, which in the young is apt to run a normal course, since the heart and the vessels are generally healthy, is often fatal when combined with this complication. Traumatic lesions and surgical intervention are to be dreaded with this complication. The writer intends, at a later date, to go more into the details of this subject.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, June 22, 1902.

Medicated Milk.—O. Macé by this term means milk that is modified by the administration of drugs to the mother, in order to treat a sick child at the breast. Experiments have been made by certain authorities of giving food rich in phosphates to animals giving milk. Sometimes they have mixed phosphate of soda in the drinking water of the animal. The quantity of the phosphates has been thus doubled in the milk. If parallel experiments have been made on nursing women, the results have never been published. As to milk charged with mercury, the passage of the drug is slow and irregular and varies with the individual, with the quantity of the drug absorbed or injected. Too much faith must not be put in this method. Experiments have also been tried with the iodides. The quantity eliminated by the milk is about half of that eliminated by the urine. The whole subject is still in an uncertain state, and even now it is not known what dose will pass on to the infant, so that the treatment is more or less inexact —*Journal des Praticiens*, June 21, 1902.

Peritonitis Following Attempted Abortion.—Varnier reports the case of a woman who confessed that she had tried to commit an abortion upon herself. She had made use of a rubber sound armed with an iron wire. The woman made three different attempts to introduce the sound into the cavity of the uterus. Laparotomy showed the existence of an area in the upper, anterior surface of the uterus, which was surrounded by a liquid suggestive of septic peritonitis. Hysterectomy was performed. The placenta was discovered to have remained in a posterior cavity, which communicated with the rest of the uterus only by a filiform canal. The writer thinks that this woman was able with ease to introduce the sound into her uterine cavity, from what he has learned in this respect from experimental researches.—*La Presse Médicale*, June 21, 1902.

A Case of Syphilitic Hysteria Diagnosed Surgically.—Francesco Camaggio reports the case of a young woman suffering from hysteria of such severity that her physicians, after exhausting all possible treatment, advised sending her to an asylum. Called in consultation, the author happening to ascertain that the girl's mother had been operated on for cancer of the breast twenty years before, and had had no return of the trouble, strongly suspected that the so-called cancer had been a syphilitic lesion, and that the daughter was suffering from hereditary syphilis. At the age of twelve she had had some affection of the eyes and swelling of the knee. The author advised mercurial treatment, but the physicians who had the case in charge refused to believe in the theory of syphilis and continued the injections of morphine, upon which the author retired from the case. The girl's father, however, had been impressed with the possibility of a cure, and unknown to the attending physician, put a mercurial solution in the bottle supposed to contain the solution of morphine. The result was miraculous; after three injections the patient came to her senses and made inquiries as to what had happened since her last recollection of events, months before—after ten injections she was physically cured, and after twenty-four was so changed physically as to be unrecognizable. The attending physicians claimed the credit of having cured her with the morphine, upon which the parents were unable to refrain from a confession of the substitution practised.—*Giornale Internazionale delle Scienze Mediche*, June 15, 1902.

Bulletin of The Johns Hopkins Hospital, June, 1902.

Peripheral Venous Thrombosis in Pneumonia, with Report of Three Cases and a Review of Those Previously Recorded. Abstract.—Walter R. Steiner says that the rarity of thrombosis in pneumonia should be noted. Only thirty-eight cases could be collected. This may seem strange since pneumonia is a disease in which the blood is especially rich in the elements that are necessary for clotting. In twenty-seven out of the thirty-two cases which gave fairly full statistics the thrombosis occurred during convalescence; in one it was on the day of the crisis, and in four during the course of the disease. Thus it must be generally regarded as a sequela and not as a complication of pneumonia. The lower extremities were always involved. The thrombi are mostly found on the left femoral vein. There was one case, Vulpian's, in which there was a clot also formed in the right pulmonary artery. Another case in the Johns Hopkins Hospital, showed a thrombosis of the left jugular vein, but autopsy was not permitted. Of forty-one cases death occurred in nine, while twenty-five recovered. Eight of those who died had autopsies, and in five death was due to pulmonary embolism.

Malarial Fever in Infancy, Probably Maternal in Origin.—Lindsay Peters reports the case of a woman twenty-seven years of age who suffered from malarial paroxysms during her pregnancy. Shortly before the birth of the child she had a severe shaking chill, followed by fever and sweating. The baby was a well-formed boy, weighing seven pounds. Blood specimens taken from his ear on the second and third days after birth were hastily examined and showed no organisms. On the fiftieth day after her confinement examination showed that the child was very anæmic, the skin having a faint, yellowish tint The lower border of the spleen was about 3 cm. below the costal margin Examination of the blood showed it to be very pale and watery, while it coagulated very slowly Three malarial parasites of the tertian variety were found Quinine was given and the anæmia and other symptoms disappeared within a few weeks The mother said that she had noticed that the baby, since the second week after birth, "got cold and had fevers" from time to time From the history and from the high grade of anæmia, it is evident that the infection was not recent, hence it must have been acquired, either in utero or very soon after birth The writer is inclined to think that it was an intrauterine infection.

Acute General Gonorrhœal Peritonitis.—Guy L. Hunner and Norman MacL. Harris, from their observations in a series of cases of general peritonitis due to the gonococcus, are convinced that surgical measures in this affection are of doubtful therapeutic value. But the question of differential diagnosis will always need careful discrimination and in doubtful cases operation should be performed. If the peritoneal cavity is entered, and a dry, plastic peritonitis, characteristic of gonorrhœal infection is discovered, the intestines should be disturbed as little as possible. If the tubes contain pus in appreciable quantities they should be removed. When pus tubes or a pelvic abscess are operated on by puncture *per vaginam*, irrigation should never be used. The symptoms of an acute gonorrhœal peritonitis are similar to the symptoms of other forms of general peritonitis. The clinical history of the disease, is, however, characteristic. The onset is very acute and violent. In a few days the symptoms subside, recovery is rapid, and there generally remains an intraperitoneal exudate, pelvic adhesions or pus tubes. This disease seems to be particularly fatal to children. This is probably due, in great measure, to the fact that children will not remain still. For the treatment of this disease should consist in absolute rest in bed, hot turpentine stupes, alternating every half hour with hot-water stupes, mild catharsis, liquid diet cold sponges for the high temperature, and stimulative treatment, according to the severity of the symptoms.

Russki Arkhiv Patologii, etc., May 31, 1902.

Certain Biological Differences between the Macro- and Microphages.—Sawtchenko demonstrates, by a number of examples, that macrophages contain in their protoplasm a cystase which possesses the property, under certain conditions (notably in the presence of a specific fixative), of easily digesting microbes. He explains the difference in the sensitiveness of micro- and macrophages toward various microbes, by the different composition of the fixative in the protoplasm of the various forms of leucocytes.

The Etiology, Pathogenesis, and Bacteriology of Simple Ulcers in Man, and Their Experimental Reproduction in Animals.—S. Timofeeff says that the microscopical examination of forty-seven cases of simple ulcer has shown that in the granular tissue and in the skin wounds which are transformed into ulcers, an amyloid degeneration occurs, which, however, is absent if ulceration does not take place. Cultures of the pus from these ulcers has shown the staphylococcus, the coli communis, and the pyocyaneus. In rare cases the bacilli lactis ærogenes, pyogenes fetidus, thyphi, subtilis, fluorescens liquefaciens, pneumo-bacillus Friedlander, diplococcus Fraenkel, streptococcus brevis, a bacillus resembling the bac. choleræ galinarum, aspergillus niger, and aspergillus fumigatus, have been found. Living cultures of the staphylococcus albus and bac. coli communis when injected in the subcutaneous tissue of rabbits, reproduced amyloid degeneration.

Subcutaneous Injections of Gelatin in the Treatment of Aneurysm.—N. V. Verchinine concludes from his investigations that this form of treatment has frequently been of the greatest service. The following points are to be borne in mind: (1) Injections of gelatin give positive results in the case of sacculated aneurysm, not complicated by serious alterations or concomitant effections of the vital organs. Otherwise the gelatin may be unable to prevent the development of the morbid process; (2) It follows that gelatin treatment should be initiated as early in the disease as possible; (3) It should be applied in a systematic manner, and, according to the severity of the case, will be suspended and reapplied at intervals; (4) The individual sensitiveness to the concentration and amount of gelatin to be injected should be carefully ascertained; (5) The injection should be made very slowly, and, of course, under antiseptic precautions; (6) A cure is not obtained by means of the destruction of the aneurysmal sac. Gelatin apparently acts by diminishing the volume of the sac and by thickening its walls.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE ILLNESS OF THE KING.

London, July, 1902.

The clinical history of His Majesty's malady is not so very unusual. You have heard that he seemed to have caught a chill and had vague pains attributed to rheumatism which compelled him to rest a little, and with the great ceremonial in front made him cancel some previous engagements. These vague pains recurred and, together with intestinal derangement, suggested graver disturbance. His Majesty was anxiously watched and the least symptom noted. The pains became localized and inflammation of the appendix vermiformis was indicated. This subsided, as it so often does, and it was hoped that the King might be able to carry out his great program. But recurrence took place too soon. It was clear at the consultation that suppuration had occurred, and an abdominal operation the only means of saving the King's life. It is said that, on being told that it was necessary, his Majesty said: "Operation or no operation, I must go to the abbey. I will not disappoint the people." Other sayings are circulated, all founded on the well-known character and cool fortitude of the King, who, when compelled to yield, displayed his usual courage and bowed to the inevitable. This mental attitude and a strong constitution stand him in good stead, and the satisfactory progress since leads us to look with some confidence for His Majesty's restoration.

The bulletins issued the next day were satisfactory, though expressed with caution. There had been a fair amount of sleep. On Thursday morning the news rapidly spread that the King had had a better night, and in the forenoon the bulletin, signed by all five of the medical attendants, confirmed this, spoke of refreshing sleep and said the King had "improved in all respects, his constitutional condition was quite favorable, and the state of the wound also satisfactory." This, after the second night, was all that could be expected. The evening's report by the same five consultants was that the King had passed a good day and taken nourishment well, was less weak, and the temperature normal. Later, at 11 P.M., it was added that he had maintained his strength and there was a returning desire for food. There had been some pain in the wound. In the morning it was stated that the King had had a fair night with some natural sleep. Appetite improving. The wound much more comfortable and, on the whole, the condition attended with less anxiety. In the afternoon the bulletin stated he had passed a comfortable morning and all the symptoms were satisfactory. The temperature still normal.

Our newspapers now contain little which does not, in some way, relate to the one subject of public interest. Estimates of the losses it entails on many and the direct ruin of some; amusing attempts of the versatile reporter to describe perityphlitis and instruct the public how to distinguish it from appendicitis, and even efforts to prognosticate results; full descriptions of crowds around the palace and of watchers pacing the streets to a late hour to see the last bulletin, and of some even watching the place all through the night; the services of intercession at the many places of worship; these all, no doubt, interest their readers and do no harm. But there is one thing to be condemned—the circulation of disquieting rumors for which there is no foundation. Some have not hesitated to repeat the old story that the King had cancer, and add to it that this operation was for that disease. Yet they must know that the Court physicians have over and over again denied it. One paper has even gone so far as to rebuke Sir F. Treves for the assurance he gave the public in a speech last November, and insinuate that he must have foreseen such a result. Of course it is not the high-class papers which are guilty of this, though some that pretend to respectability have erred—perhaps from lack of editorial supervision or calm judgment on so all-absorbing a subject at a time of such excitement.

Summing up the features of the case, the King's temperature has continued normal and he has had good nights. The latest bulletins speak of comfortable days, refreshing sleep at night, improvement of general condition, and less pain in the wound. This is dressed twice a day and the process causes distress, but his Majesty's fortitude never fails, to the delight of the surgeons and others. The drainage tubes have been removed and gauze plugs substituted. The discharge is diminished and quite inodorous, and granulation is proceeding satisfactorily. In fact, both locally and generally, there is promise of uninterrupted recovery.

The honors' list was at first among the things to be postponed, but this intention was altered by the King's own command, and he ordered the name of Sir F. Treves to be added, conferring on him a barouetcy. There are a number of other medical men in the list which has just appeared, but the names are scarcely discussed—all mention of them in conversation leading off to the prospects of the King.

A new "order of merit" is instituted by the King on the most exclusive basis. It is akin to the Prussian order of the same name, and will be conferred only on men of the highest distinction in literature, science, art, or naval and military service to the country. It will carry no title, no precedence, and no letters after the name. Only twelve men are included in the first list of this "most distinguished" order, and among those twelve is Lord Lister.

Surgical Suggestions.

Disinfectant Solutions of proved potency in destroying the plague bacillus are bichloride of mercury (1-1000), chloride of lime (1-100), caustic lime (1-100), carbolic acid (5-100). James Cantlie.

Treatment of Wounds.—Unless you suspect that the wound is not aseptic let it alone, for blood is a better antiseptic than water or blood diluted. Remove all clots and secure all bleeding vessels before closing the wound. For oozing apply hot lint or cotton mops wrung out of sterilized water and maintain pressure for a few moments. H. J. Banker.

Ectopic Gestation.—If called to a patient with a history of possible ectopic pregnancy who has just had severe pain in the pelvis, vomiting, fainting, pallor, with a weak voice and a rapid, feeble pulse, with abdominal tenderness, we should operate without delay.

H. F. Twitchell.

In Tetanus keep the patient in a dark room, where all is quiet and allow no visitors; give morphine and atropine hypodermatically, alteratives and sedatives in combination in large doses. Watch the case. Give chloroform to relieve spasms. E. D. O'Neill.

Articles for Handy Use in Obstetrics.—Hot and cold water, fountain syringe, hot-water bottle, scissors, sterilized sheets and towels, soft-rubber catheter, drinking cup, bed-pan, rubber sheets, antiseptic pads, and solution, plenty of light and pure air, safety pins. These, together with a good nurse and obstetrician, and with some good aseptic lubricant, mixed with the oil of patience and intelligent manipulation and care, will result in much being accomplished in confinement cases.

Willington Johnson.

Modern Method of Vaccination.—The skin is disinfected with warm boracic-acid solution. The lymph is then blown upon the skin, the skin put upon the stretch, and scarification accomplished through the layer of lymph by means of an ordinary triangular-headed surgical needle. In this way the corium is thoroughly opened up and the emulsion brought into direct relation with the cells of the true skin. Copeman.

For Aborting Buboes Christian applies eight parts each of ung. hydrargyri, ung. belladonnæ, ichthyol and lanolin or lint every second day. It is his opinion that at least half of the buboes due to gonorrhœa, herpes, and chancroid can be aborted if treated before suppuration has commenced.

Hydrogen Peroxide by softening the dried blood and serum is excellent for separating adherent dressings.

In Chronic Gonorrhœa, which has resisted all other methods of treatment. H. de Bran has obtained rapid and final cures from injections of picric acid in strengths of 1–200 and 1–100. In acute gonorrhœa one, two, or three injections daily, depending upon the pain experienced, are said to produce a cure in four or five days.

Fissured Nipples are cured by the application of a 3 to 5-per-cent. solution of potassium permanganate. The first applications are painful, but the pain soon disappears.

—Dombrovsky.

Book Reviews.

Acute Dilatation of the Stomach. By H. Campbell Thomson, M.D., M.R.C.P. New York: Wm. Wood & Co., 1902.

In the present monograph Thomson describes four cases of acute dilatation of the stomach. All the patients suffered from vomiting and collapse and did not respond to any medication; they ended fatally a few days after the onset of the disease. At the autopsy no obstruction of the pylorus was found in three of the cases, while it existed in one. In the latter case acute dilatation in consequence of chronic obstruction of the pylorus. As the disease is such an important one, both in its connection with medicine and surgery, this summary of its chief characteristics, together with the collection of recorded cases, will certainly prove useful.

Operations-Vademecum für den praktischen Arzt, von Dr. Edmund Leser, Professor an der Universität Halle, etc. Mit 84 Abbildungen. Zweite Vermehrte und Verbesserte Auflage. Berlin: S. Karger, 1902.

The second edition of this handbook on operative surgery is in some ways an improvement upon the first, though the new photographic illustrations mentioned in the preface with apparent pride are, as a rule, very poor, and have all the faults of such illustrations when poorly executed. The text conforms very closely to that of the first edition, which had considerable merit in its field, and does not, therefore, require extended comment. Descriptions of a number of recent surgical achievements have been added, in order to make the present issue meet present-day requirements.

Reports on Plans for the Extermination of Mosquitos on the North Shore of Long Island. New York: North Shore Improvement Association, 1902.

This volume (125 pages octavo, with large wall-map) is an elaborate and convincing argument for the practical success of anti-mosquito work anywhere along the Atlantic Coast. The North Shore plans originated with Mr. W. J. Matheson's successful work at Cold Spring Harbor in 1900, conducted under the direction of D. L. O. Howard of the N. S. Department of Agriculture. The present book contains reports by Mr. Henry Clay Weeks, Consulting Engineer, on the general problem to be solved, and on the specific steps to be taken with the marshes, salt ponds, lakes, and all the innumerable domestic accommodations of water throughout the territory. Mr. Weeks adds an appendix on the work of last year at Center Island, which was conducted under difficulties, but proved a gratifying success. Entomological reports on the local conditions are furnished by Prof. Chas. B. Davenport and Mr. Frank E. Lutz of the University of Chicago. Prof. N. S. Shaler of Harvard University reports on the marsh areas, and the economic questions concerned in their reclamation. The measures recommended are comparatively simple, and, barring the problems involved in draining large areas, surprisingly inexpensive. Drainage, cleaning of the margins of permanent streams, mill-ponds and lakes, and the destruction or petrolization of domestic accumulations of standing water, are the principal means recommended, with the additional agency of small fish in some instances, to destroy larvæ not destructible by any other means. The success of this work, as a whole, is already assured, and if the same enlightened and practical methods be adopted elsewhere, we may look forward to the time when the mosquito-plague, with torment and disease following in its wake, will be only a matter of history along the Atlantic Coast.

A Manual of Surgical Treatment. By W. Watson Cheyne, M.B., F.R.C.S., F.R.S., Professor of Surgery in King's College, London, etc., and F. F. Burghard, M.D., and M.S. (Lond.), F.R.C.S., Teacher of Practical Surgery in King's College, London, etc. Volume VI. The treatment of the Surgical Affections of the Tongue and Floor of the Mouth, the Pharynx, Neck, Œsophagus, Stomach and Intestines. Philadelphia and New York: Lea Brothers & Co., 1902.

The contents of this sixth section of Cheyne and Burghard's comprehensive work are pretty well indicated by the title page. As in the earlier sections, the authors have given us satisfactory descriptions and adequate illustrations and have endeavored to keep matters well up in surgical progress. Some of the chapters are very full and may be called excellent, while others leave something to be desired from every point of view. Among the latter we may place that on appendicitis, which does not cover the subject satisfactorily, according to our judgment. On the appearance of the next volume, we may congratulate the authors upon the completion of their task, and ourselves upon the possession of an excellent textbook in the field of surgery.

Sewage and the Bacterial Purification of Sewage. By Samuel Rideal. Second edition. New York: John Wiley & Sons, 1901.

The scope of this book of 300 pages is comprehensive, the arrangement is excellent, and the author speaks with authority on the subject of which he treats. The work is very valuable and should be read by all interested in sanitation and its most difficult problem—the disposal of excreta. The discussion of the development of the bacterial treatment of sewage, presenting, as it does, the most scientific and satisfactory method of sewage disposal, is very complete, and is brought fully up to the most recent advances in our knowledge of this subject.

The Medical Treatment of Gallstones. By J. H. Keay, A.M., M.D. Philadelphia: P. Blakiston Sons & Co., 1902.

The treatment of cholelithiasis, upon a rational clinical basis, has not been advanced by Dr. Keay's contribution. The author errs if he thinks that the surgeon is ready and willing to operate upon all individuals who are thought to have gallstones. On the contrary, such patients are treated medically, until, either from the oft-repeated recurrence of biliary pain and colic, or on account of acute inflammation of the gall-bladder, or from some other complication in the gall-bladder and ducts, an operation becomes indicated.

Of the 100,000 persons in the British Isles afflicted with gallstones (Keay's statistics) it was those with recurrent attacks of acute cholecystitis that constituted the 2,000 who were operated upon within the last ten years. The other 98,000 suffered merely with attacks of biliary colic, which, though intensely painful, is not a cause of death. Why should Dr. Keay be surprised then that the mortality in these 98,000 cases, treated medically, is low. The surgeon has to contend with acute inflammatory lesions attended with sepsis. If his statistics in these cases are compared with those of the internists in similar cases, an astounding difference in his favor would be discovered.

Under empyema of the gall-bladder the author writes as follows: "For the escape of pus nature has provided a method which is often quite as satisfactory as surgical drainage. If the bile ducts be open an escape for the pus is provided; further, an inflow of healthy bile may provide for the destruction or removal of the streptococci." Surely the author cannot seriously entertain the meaning of this statement. If the bile-ducts are open, how can there be an empyema of the gall-bladder? The very first essential for the establishment of an empyema is a closure of the cystic or common ducts. When this closure is spontaneously relieved, the empyema disappears without operation. If the doctor will tell us how to tell positively in which cases this spontaneous relief will occur, the question of when to invoke surgical aid will be very readily solved. But if such a fine prediction, as to what will happen in any one particular case, cannot be made, it is certainly far more rational to incise and drain a large pus sac than to permit a patient to carry around such a sword of Damocles, that threatens to descend upon his bared neck at any moment.

Visual Economics, with Rules for Estimation of the Earning Ability after Injuries to the Eyes. By H. Magnus, Med. Dr. of Breslau, Germany (Professor of Ophthalmology in the University of Breslau, etc.) and H. V. Wurdemann, M.D., of Milwaukee, Wis., U. S. A (Professor of Ophthalmology to the Milwaukee Medical College, etc.). For the use of the Medical and Legal Professions, Business Corporations and Insurance Officials. Milwaukee, Wis.: C. Porth, 1902.

Works devoted to the medicolegal bearing of partial or complete loss of vision from any cause whatsoever have heretofore been meagre and fractional in English ophthalmic literature. With the advent of this work we have presented an elaboration of the work of Prof. Magnus of Breslau, which is a recognized standard reference book in questions of this nature in Germany. Important additions have been made and the whole adapted to the requirements of American law. The volume, which consists of 142 pages with test type and various other plates added, is divided into four parts. Part first is devoted to the consideration of: "The legal status of the physician in relation to accident insurance and indemnity for accidents," etc. Part second takes up the "special consideration of various ocular injuries and visual defects." Part third, "Estimation of the pecuniary loss to the individual by reason of visual imperfections." Part fourth "Tables for estimation of the different forms of damage to the visual earning ability." The work evidences a most careful study of the economics of vision. The estimation of damages is reduced to mathematical formulæ, apparently on a rational, equable basis, sufficiently comprehensive to embrace all cases. The book is authoritative and should be in the library of every ophthalmologist. Physicians, casualty insurance companies, and manufacturers will find it a valuable aid in adjusting claims for injuries affecting vision.

De la Conjonctivite Granuleuse par le Dr. Z. Hourmouziadès, Aide de Clinique Ophthalmologique à l'Hospice National des Quinze-vingts. Avec Preface par le Dr. A. Trousseau, Médecin de la Clinique Nationale Ophthalmologique des Quinze-vingts. Paris: Société d'Éditions Scientifiques et Littéraires, 1902.

The first chapter of this small volume of 190 pages is devoted to a consideration of the anatomy of the conjunctiva. Then follows an historical sketch of granular conjunctivitis: subsequent portions of the text are devoted to the pathology of trachoma, its symptoms, duration, consequences, etiology, treatment, and treatment of the results of the disease. A few illustrations, the greater number of which are from other works, appear in the text. The author presents the current European views of the subject in a systematic and attractive manner. The work will be read with interest by many ophthalmologists.

The Surgery of the Rectum. By Charles B. Kelsey, A.M., M.D., Late Professor of Pelvic and Abdominal Surgery at the New York Post-Graduate Hospital, and Professor of Rectal Surgery in the University of Vermont, etc. Sixth Edition. Illustrated by 215 Engravings. New York: William Wood & Co., 1902.

The fact that this book is in its sixth edition is sufficient evidence of its popularity, and desirable qualities. Its author has long been well known in his specialty, and his opinions will always have weight. The present edition has been largely rewritten, and considerable new matter has been introduced in order to include certain advances and novelties in rectal surgery. The author's personal experience has been largely drawn upon, but the work of other men is by no means excluded, and a number of important chapters on the surgery of regions and organs immediately adjacent to the rectum have been introduced. As in previous editions, there are many useful and well-executed illustrations.

Diseases of the Nose, Pharynx and Ear. By Henry Gradle, M.D., Professor of Ophthalmology and Otology in the Northwestern University Medical School, Chicago. Pp. 547. Philadelphia and London: W. B. Saunders & Co., 1902.

This volume is in essence the record of a busy life of nearly twenty-five years' duration. From the author's long clinical experience, he has endeavored to provide a manual which should answer the many questions presenting themselves to the less experienced clinician, particularly in reference to those points not usually mentioned in the routine textbooks. No claim is made to the literary and historical completeness properly looked for in an encyclopedic treatise. Special attention has been given to topographical anatomy. The therapeutic measures recommended are those that have stood the test of the author's personal experience.

A review of the book convinces us that the goal aimed at has been fairly well attained. Naturally, all such books repeat much that has been already written, but there is in a clinical experience a personality that stamps each publication. The author has produced a work that is most creditable, alike to himself and to American rhinology and otology.

Les Fonctions Hépatiques. Par A. Gilbert et P. Carnot. Paris: C. Naud, 1902.

In man the liver represents the biggest and also most important gland of the system. The present manual deals in detail with all the varied functions of this organ. The liver is imbued with two kinds of secretions, one intern and another extern. The intern secretion of the liver has been discovered by C. Bernard, who proved its glycogenic action. This intern secretion has a bearing on the composition of the blood, its amount of iron, fibrin, and ferments; it also acts on the alimentary substances and arrests toxic products. The book is very well written and is of great interest to the physiologist as well as to the physician.

The Practical Medicine Series of Year Books, comprising ten volumes in the year's progress in medicine and surgery. Issued monthly under the general editorial charge of Gustavus P. Head, M.D., Professor of Laryngology and Rhinology, Chicago Post-Graduate Medical School. Vol. V, Obstetrics, Edited by Reuben Peterson, A.B., M.D., Professor of Obstetrics and Gynecology in the University of Michigan, and Henry F. Lewis, A.B., M D., Instructor in Obstetrics and Gynecology in Rush Medical College. Pp. 233. Chicago: The Year Book Publishers, 1902.

The purpose of this edition, as expressed in the introduction, to present "the digested views of the best writers . . . during the past twelvemonth" is carried out with fair success in this year-book.

Considerable attention is bestowed upon *syncytioma malignum*. It is interesting to note that the subject of placenta prævia has by no means been exhausted, judging by the number of articles that have appeared. Hyperæmesis gravidarum has apparently been of general interest, though it must be confessed that the treatment is quite as unsatisfactory as ever. Eclampsia covers seventeen pages, as its importance deserves; the same comment applies to extrauterine pregnancy, to which twelve are given.

Part II., on Labor and Its Complications, is excellent and contains a great deal of useful information, especially under the paragraphs on asepsis, spinal anæsthesia, dystocia, and malpresentations.

Puerperal infection, the most important section in Part III, covers ten pages, but contains little that is new. Part IV, on Obstetric Surgery, is short, but up to date. Altogether the book is a worthy companion of the rest of the series.

Hernia: Its Ætiology, Symptoms and Treatment. By Wm. McAdam Eccles, M.S., F.R.C.S. Second Edition, 233 pages, profusely illustrated. New York: Wm. Wood & Co., 1902.

Dr. Eccles is again to be congratulated on the appearance of the second edition of his book. Few changes have been made in the text, but new illustrations have been added. The student and the profession at large will gladly receive the work, for the subject of hernia is treated in its every detail, clearly, concisely, and accurately. The numerous excellent illustrations add very much to the value of the book. The publishers are also to be congratulated for their exceptionally fine book making.

Sanatoria for Consumptives. By S. Rufenacht Walters, M.D. Second Edition, pp. 446. $5.00 net. London: Swan Sonnenschein & Co., Lim. New York: E. P. Dutton & Co., 1902.

The sanatorium movement is now engaging the attention of the medical profession in all civilized countries, and any work giving up-to-date information on sanatoria must be a welcome addition to the literature on the subject. Up to page 318 this book is an exact reproduction of the first volume, which appeared in 1899. The chapter on British institutions has been rewritten and must be considered as the best recent account of the sanatorium movement in England. In the appendix of the present edition Dr. Walters summarizes recent changes in foreign countries up to 1902. It is to be regretted, however, that the author has not taken more pains in getting exact information concerning foreign institutions. For example, he describes the Pasteur Sanatorium, near New York, which has been extinct for nearly two years, and he omits to mention the first and one of the most important municipal hospitals for consumptives in America, erected in Cincinnati a number of years ago. The most modern and magnificent German establishment, the Wehrawald Sanatorium, considered a model institution, which was built in 1900 and has been in existence for over a year, does not receive any mention. The chapters on climatology, treatment, management of sanatoria, and prophylaxis are the same as in the first volume. To us it seems a serious omission that in the chapter treating of sputum and disinfection not a word is said in regard to drop-infection, a factor of contagion which must always be considered in institutions where there is an aggregation of consumptives. Taking it all in all, however, we have before us a work which is well worth perusing by all interested in the institutional treatment of consumptives, and the book will certainly help to stimulate the sanatorium movement throughout the civilized world.

The Physiological Pathology of the Circulation in Acute Pneumonia.—A. S. Maschke says that, aside from minor factors, the sum of our knowledge of the state of the circulation in pneumonia is as follows: The deleterious action of pneumonia on the circulation is primarily due to the accompanying toxæmia, not to the fever *per se*, but may possibly be secondarily somewhat influenced by the mechanic obstruction. The toxæmia produces this circulatory depression, not by poisoning the heart or the heart centers, and nerves, but by directly poisoning the vasomotor centers in the prolonged cord, and thus producing a vascular dilatation. The heart is affected only late in pneumonia, and then because of its own deficient coronary circulation brought about by the abnormal distribution of the blood-supply.—*The Cleveland Medical Journal.*

Therapeutic Hints.

Constipation.—

℞	Sulphuris loti	āā ʒi.
	Potass. bitartratis	
	Pulv. sennæ	ʒss.

Hyperexcitability of Stomach with Pyloric Spasm, etc.—

℞	Hydrat. chloral	gr. xv.
	Aquæ	℥iss.

From 15-30 drops in water after each meal.

Hydriatic Treatment of Pneumonia.—The best way to combat local congestion of the lungs is to produce a cutaneous hyperæmia of skin of back by prolonged applications of heat to the back, alternating once an hour with cold applications, as this will increase the physiological action of the heart. Apply during the early stages of disease cold or ice compresses to chest, being careful not to chill the tissues. Cold to chest causes contraction of surface vessels and to the pulmonary vessels. Copious draughts of water, enemas, short-sweating packs, and short, hot baths will encourage the illumination of poisons. All hot applications should be supplemented by short cold treatment. The dietary should consist of well-dextrinized cereals and easily-digested fruit rather than fresh foods.

David Paulson.

Burns in Infancy and Childhood.—When more than one-third of cutaneous surface is involved in burns the outlook is unfavorable. Aromatic spirits of ammonia is recommended to meet indications of vital depression. Opium in doses proportionate to age produces quieting effect. Picric acid in 1 per cent. watery solution gives almost immediate relief from pain and healing takes place rapidly. It is best not to remove dressing next to skin, but simply wet and cover with absorbent cotton; this diminishes pain and danger of outside infection. Iodoform is objectionable on account of odor and danger of iodoform dermatitis. Permanent bath is, perhaps, the best means of offering comfort in deeper and more severe burns. Cotton oil is best for soothing. Most important point is to refrain from removal of dressings.

—Allen.

Tabes.—Negro has used santonin in from 5-20 grains every three hours for the relief of the lancinating pains of tabes, with great success.

Pertussis.—J. D. Kelly states that he has witnessed favorable results from the use of calcium sulphide in the treatment of pertussis. He gives one grain every four hours to a child five years of age.

Sciatica.—Kuhn states that deep injections of antipyrin, at a point midway between the great trochanter and the tuberosity of the ischium, will relieve the pain of sciatica.

Decinormal Salt Solution in Cholera.—Salt solution supplies fluid to the anhydræmic blood, it replaces the loss of heat, dilutes the thickened tissue fluids, stimulates the kidneys to action, and aids in eliminating toxic material circulating in the blood and exercising deleterious effects upon the tissues and nervous system.

G. A. Himmelsbach.

The Ocular Expressions of Renal Disease.—Howard McI. Morton says that renal changes, however distinctive, are not of themselves conclusive evidence of Bright's disease. But their value, while not absolute, is great, and in the presence of urinary symptoms of a confirmatory nature, is absolute, and their prognostic importance is then both great and grave. The typical picture of albuminuric retinitis is characterized clinically by hemorrhage in the retina, white spots of degeneration and neuritis, with sclerosis of the fibers of Muller, which give a characteristic stellate arrangement of white spots about the macula. These changes are usually bilateral, symmetrical, and of about equal severity. Uræmic amaurosis may occur in any of the various forms of renal disease in which renal insufficiency permits the accumulation of certain toxic materials. Tirard thinks that the uræmic blindness of acute nephritis is a transient symptom, and its short duration very marked in comparison to prolonged blindness of the uræmia of chronic nephritis. Its occurrence in pregnancy is a grave symptom. The prognosis of retinitis occurring in the albuminuria of pregnancy is far less unfavorable in regard to both vision and life than in the other forms of renal retinitis. The retinal changes of diabetes are rare, and afford nothing distinctive of sugar in the urine. Cataract occurring in these cases is common. Optic atrophy occasionally occurs. It is well known that œdema of the integument of the lower lid takes place in the general œdema of the terminal stages of chronic kidney disease. Œdema of the conjunctiva occurs, but is rare. —*Northwestern Lancet.*

The Surgical Significance of Carbuncle of the Upper Lip and Face.—James E. Moore holds that with our present knowledge of this disease we are warranted in the conclusion that the so-called conservative or expectant treatment is only applicable to those cases in which the disease is so situated and is of so mild a character that the natural tendency is toward recovery. It certainly never is indicated when the disease is on the upper lip and face. When in this location, the disease is accompanied by a mortality of 50 per cent., and is not to be trifled with. It is the physician's imperative duty to urge early operation, then if the patient or his parents refuse consent the responsibility is theirs. The highest success obtainable is secured by very early diagnosis, and prompt treatment, for by this course we save our patient, and the scar is insignificant.—*The St. Paul Medical Journal.*

Society Reports.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Twenty-fourth Annual Congress, Held in Boston, Mass., May 26, 27 *and* 28, 1902.

John W. Farlow, M.D., of Boston, President.

First Day—Monday, May 26.

The meeting was called to order by the President, Dr. John W. Farlow of Boston, in the Boston Medical Library.

President's Address.—Dr. Farlow began his address by pointing out the great variety of subjects treated of in the program of this meeting as compared with that of the last meeting held in Boston, ten years ago. This he took to be a fair indication of the widening scope of their specialty. To show what kind of instruction was needed at the present time in this department the speaker described the clinical exercises and lectures which are given in the laryngological department of Harvard. The complaints of their patients could be broadly classed under two headings, viz., (1) Those due to nasal obstruction, and (2) Those dependent upon increased secretion. The feeling of a need of air occurs in anæmia, debility, over-work and in a great variety of other disorders. He felt that the use of cocaine had incited too much unnecessary nasal surgery. Much experience and skill were necessary in order to recognize by digital examination, without an anæsthetic, the existence of adenoid hypertrophy. In his opinion, the relation of the nose and throat to voice production had not received the attention it deserved.

Tumor of the Pharynx; an Accessory Thyroid Gland; Removal Followed by Myxœdema.—Dr. E. L. Shurly of Detroit presented this report. The patient, a girl of sixteen, was apparently well nourished, and examination revealed neither enlargement nor diminution of the thyroid gland. There was a tumor, about the size of a hen's egg, attached at the base of the tongue, a little to the right of the median line and near the epiglottis. His diagnosis was adenoma. The tumor was removed by means of a snare under chloroform anæsthesia, pharyngotomy not being considered desirable because of the resulting scar. The operation was followed by rather persistent hemorrhage. Some time afterward she was brought back to him with well-marked myxœdema. She was then put upon thyroid extract, five grains, three times a day. The speaker said that about twenty-five cases of accessory thyroids of the tongue or pharynx had been reported by American surgeons. In all of these there had been an absence of serious subjective or objective symptoms, and myxœdema had been noted only rarely after removal.

Dr. F. I. Knight of Boston and Dr. W. E. Casselberry of Chicago reported somewhat similar cases.

Subglottic Sarcoma; Removal Endolaryngeally with Galvanocautery Snare.—Dr. J. W. Gleitsmann of New York read this paper, reporting a case (see Medical Record, July 5, 1902, page 12).

Dr. John N. Mackenzie of Baltimore thought the operation through the mouth for laryngeal cancer was unworthy of serious consideration, for it was impossible to map out laryngoscopically the entire extent of the morbid process; this could not be done even after division of the thyroid, or, as he had shown on several occasions, after extirpation of the larynx itself.

Dr. D. Bryson Delavan of New York said he understood the case under discussion was one of sarcoma and not carcinoma; it was well known that carcinoma was not to be treated in this way. He was not so sure as the first speaker regarding the value of the external operation in all cases, and certainly the achievement chronicled in this report was an exceedingly important one and afforded proof that there were still some laryngologists possessed of the old-time skill.

Dr. W. Kelly Simpson of New York said that the tumor had a pedicle and presented all the conditions favorable for an endolaryngeal operation. In cases of extensive malignant disease, the external operation seemed to him preferable, yet the removal of the larynx was so fatal that it was justifiable to attempt to extirpate these tumors by the mouth under favorable conditions.

Dr. Gleitsmann, in closing, said that much of the success of the operation was to be attributed to the tractability of the patient. The latter had been subjected to a course of training, consisting chiefly of breathing exercises, and after the growth had been divided by the snare, the patient was told to inhale deeply. The additional space obtained at this moment was taken advantage of for bringing the tumor upward. He thought the position taken by Dr. Mackenzie was an extreme one; it should not be forgotten that patients had been both relieved and cured by other measures than the radical operation.

A Case of Epithelioma of the Larynx; Thyrotomy; Death in Four Months.—Dr. Charles H. Knight of New York reported this case. The duration of the disease was about three years. Instead of the usual progressive development of the disease, there were periods of marked remission and positive improvement. There was tardy invasion of the lymphatics, but the involvement was speedy after surgical interference. In this case there was much contradictory microscopical testimony, a point of special interest because specimens representing the whole thickness of the growth had been submitted to the pathologists for examination. Careful and prolonged study of all the symptoms, both subjective and objective, were necessary in cases of this kind. A cancer of the larynx, so extensive as to demand complete removal of that organ with the adjacent parts, was not operable. The age, temperament, environment, and general condition of the patient must be taken into consideration, as well as the character of the growth.

Dr. John N. Mackenzie said that he had been severely criticised for making the statement that thyrotomy with curettage or removal of all the visible portions of the neoplasm, was in direct defiance of the rules which should govern us in the treatment of carcinoma, and was a return to a method of treatment that had been abandoned over a century ago.

Dr. H. L. Swain of New Haven said that if a case presented itself, which was limited in extent, and there seemed to be a fair chance for a good result from the simpler methods, he would always feel justified in adopting these before resorting to the terrible surgical operations advised by some. If these cases were to be operated upon at all, however, it was folly to do a thyrotomy and attempt by scraping to get rid of the growth. The removal of the larynx and all of the neighboring glands should be done; if this were denied, then the patient should be left alone.

Dr. W. E. Casselberry of Chicago objected to the statement of the author that a carcinoma, so extensive as to require a complete laryngectomy for its removal, is inoperable, and reported cases in support of his contention. The two cases that had been reported here seemed to him exceptional and calculated to place in a false light the subject of the treatment of malignant disease.

Dr. D. Bryson Delavan commended to the thoughtful attention of all laryngologists a monograph just written by Dr. Frank Hartley of New York. This article demonstrated beyond all question that in certain cases complete laryngectomy is a very valuable resource. Dr. Delavan thought the discussion of two years ago had done harm rather than good, and he was sorry that his friend from Baltimore had not seen the error of his ways. It was time that we should move sharply and clearly differentiate our cases.

Dr. W. Kelly Simpson advised that the operation of removing the larynx should be undertaken only by an experienced general surgeon.

Dr. E. Fletcher Ingals of Chicago concurred with the last speaker He added that, although Dr. N. Senn was known to do a very thorough operation in cases of carcinoma of the larynx, he understood that not a single one of the persons so operated upon by this distinguished surgeon could be found alive after four years.

Dr. J. Payson Clark of Boston referred to a case operated on January 4, 1897. The growth was limited to the left vocal cord, and there was but little infiltration of the muscular tissue on that side of the larynx. A thyrotomy was done and all of the soft structures on the interior of the larynx were removed. The patient had experienced no trouble since the operation and reported that at present his voice was fairly strong.

Dr. C. H. Knight said he believed the operation in his case was an improper one, yet the patient had positively declined more radical measures. His own limited experience with the complete operation had been decidedly discouraging as regards the future of the patient.

The X-Ray in the Treatment of Malignant Disease of the Larynx.—Dr. D. Bryson Delavan of New York was the author of this paper. He said that, so far as he knew, not a single case of carcinoma of the larynx had been reported as cured by the *x*-ray. From the improvement noted in cases of *x*-ray treatment of cancer of the tonsil and pharynx, advanced and extensive cancer of the neck should be given a trial of the *x*-ray treatment. This seemed entirely justifiable when the progress of the case was not very rapid, because the effect of such treatment could usually be determined in two weeks.

Dr. H. L. Swain said that in three cases of inaccessible malignant disease the symptoms had been relieved and the progress of the disease apparently checked by the treatment. Two inoperable cases of carcinoma for adenosarcoma of the nose had exhibited the greatest improvement. In one case, after about fifteen treatments, the growth had been reduced fully one-half and the pain relieved. As the growth was internal, it was reasonable to expect improvement also in laryngeal cancer.

Dr. W. E. Casselberry of Chicago said that in one of Dr. Pusey's cases, one of deeply-situated carcinoma of the larynx, there had been so little improvement after four weeks' treatment that it was discontinued During the next four weeks, however, without any treatment, the case exhibited remarkable improvement. From this experience it seemed probable that two weeks was too short for deciding whether or not the *x*-ray would prove useful in a given case of malignant disease of the larynx.

Dr. J. Payson Clark of Boston reported the case of a man of fifty-nine years with extensive carcinomatous infiltration of one side of the larynx and a well-marked cancerous cachexia. The second and third applications of the *x*-ray relieved the pain, but the patient was too feeble to come for further treatment.

Rapid Dilatation and the Prolonged Use of Intubation Tubes in Cicatricial Occlusion and in Stenosis of the Larynx.—Dr. George A. Leland of Boston spoke of a laryngeal case in which Dr. Francis H. Williams employed the *x*-ray for a long time. For three or four months the results were quite satisfactory, but finally there was a sudden increase of subglottic infiltration, necessitating tracheotomy.

The Development of the Tonsils.—Dr. Charles S. Minot, Professor of Embryology at Harvard University, gave an interesting discourse on this subject, illustrated by models and specimens.

The Growth of the Face, and Especially of the Pharynx.—Dr. Thomas Dwight, Professor of Anatomy at Harvard, made an address on this subject, using models and novel and originally-prepared specimens to elucidate the subject.

Some Remarks on the Anatomy of the Inferior Ethmoidal Turbinate, with Particular Reference to Cell Formation.—Dr. Howard A. Lathrop, Assistant in Surgery at Harvard University, made some remarks on this subject, pointing out the surgical importance of these ethmoidal cells, and showing by lantern slides the important features brought out by his study of one thousand turbinates.

Second Day—Tuesday, May 27.

Discussion on Acute General Infections Originating in the Lymphoid Tissue of the Upper Air Tract.—Dr. J. L. Goodale of Boston opened the discussion by reviewing the pathology of the tonsil. His experiments demonstrated that finely-divided substances in the crypts of the tonsil are capable of entering the tonsils proper through the interfollicular lymph spaces. He had found a complete absence of bacteria in the tonsillar tissue proper, although the crypts might contain large numbers of them. So far as he knew, every textbook on laryngology made the erroneous statement that the leucocytes found in the tonsils are phagocytes. He did not regard the tonsils as protective organs in the sense of themselves producing phagocytic leucocytes, but rather as presenting open channels along which polynuclear leucocytes make their way from the blood vessels along the surface of the mucous membrane. The number of the leucocytes in the crypts depends directly upon the presence of substances with positive chemotaxic properties. Acute infecting bacteria multiply in the tonsillar tissue proper only when penetration has been effected into the centers of the follicles. If the interfollicular abscesses discharge into the veins, the conditions are proper for the development of a general septicæmic infection.

Dr. H. L. Swain of New Haven discussed the symptoms and treatment of tonsillar infection. He called attention to the important fact that this region is an active part of the lymphatic system. The lymph node normally is a place of detention where cells are quarantined and the lymph cleansed. It was not surprising that acute inflammation of this part of the lymphatic system should give rise to such profound constitutional disturbance. The fact that such disturbance orginated chiefly in connection with infection of the faucial or pharynx tonsil was, perhaps, explained by the more direct connection with the lymphatic trunks and their much greater mass. The tonsils were now conceived to be the point of entrance of the germs causing acute articular rheumatism. In one of the writer's cases, acute Hodgkin's disease and lymphadenoma had originated from the tonsil and had terminated fatally. Very young children were, as a rule, affected by purely third tonsil inflammation. In children of from three to six years the results of inflammation of the tonsil were apt to be very lasting. Often such an attack was ushered in with fever and with almost no local signs except, perhaps, a slight stoppage of the nose. After one or more days of fever, headache and foul breath, the attack often passed off, all the examinations of the family physician having proved negative. In a few days, perhaps, the neck would swell, the child would become genuinely ill and the diagnosis then would be lymphadenitis. These cases were especially interesting because of the absence of the marked local manifestations. Even in young children it was usually possible, by spraying out the nose with a weak solution of cocaine to make an inspection of the parts and accurately estimate the size of the third tonsil and the existence of follicular inflammation. Friedlander had recently reported that in 133 autopsies, made at the New York Foundling Hospital, tubercular lymph nodes were found in the chest in every case irrespective of the cause of death. The tubercular infection was believed to have originated in the tonsils, a belief which indicated the vast importance of the subject under discussion. In the opinion of the speaker, the tonsils should be looked upon as just as normal as other lymph nodes in the body, but if they were known to be infected or otherwise abnormal, they should be removed. The instillation of boric acid and suprarenal solution into the nose not only opened up the passages, but cleansed them. A weak solution of peroxide of hydrogen was sometimes beneficial, but its prolonged use was undesirable because of the irritation produced, and in every instance its application should be followed by an alkaline spray or wash.

Dr. E. L. Shurly of Detroit said he believed these lymph nodes, or tonsils, had an important physiological function in assisting the fermentation of food lodged there, and in the destruction of saprophytic organisms falling there.

Dr. R. C. Myles of New York was of the opinion that the normal tonsil represented from thirty to sixty cubic millimeters. Dr. Swain's experience agreed with his own.

Dr. Clarence C. Rice of New York suggested that the physician frequently aided the progress inward of infection by the use of such astringent applications as the nitrate of silver. Soothing disinfectants and relaxing gargles should be used rather than cold astringent applications.

Dr. John O. Roe of Rochester observed that the common opinion that a tonsil, when diseased and requiring removal, must be hypertrophied, was a fallacy.

Dr. George A. Leland of Boston said that, according to his experience, children affected in the way described by Dr. Swain invariably had inflammation of the middle ear.

Dr. W. E. Casselberry said that it was desirable, when treating young children, to substitute a medicine dropper for the spray, as the miniature douche that could be produced by the instantaneous propulsion of a little fluid with a medicine dropper was quite effective and could be more readily used for these patients. For diagnostic purposes he advised using as weak a solution of cocaine as 1–10 per cent.

Dr. Samuel Johnston of Baltimore advised commencing the treatment by a calomel purge, followed by citrate of magnesia. A saltspoonful of a powder, composed of 2½ drachms each of the biborate, bicarbonate and salicylate of soda, four grains of carbolic acid and four minims of oil of cassia, is to be dissolved in a tumbler of hot water and used as a gargle every half hour or hour. Under this treatment a cure was usually effected in a case of acute follicular tonsillitis, in three days.

Dr. W. Kelly Simpson of New York thought this disease was self-limited, and was affected little, if any, by any treatment.

Dr. E. Mayer of New York deplored the use of the finger for curetting or for diagnostic purposes. The presence of adenoid tissue on the posterior pharyngeal wall almost surely pointed to adenoid tissue in the nasopharynx.

Dr. E. Fletcher Ingals of Chicago believed it was possible to abort acute follicular tonsillitis by energetic measures. He now almost invariably applied a 50 per cent. solution of guaiacol and oil. It causes severe burning for about thirty seconds and then usually gives complete relief from pain for many hours. By this treatment three-fourths of the cases could be aborted, and it was worthy of trial even when the disease had existed for three or four days.

Dr. J. H. Bryan of Washington, D. C., remarked that he had suggested having a discussion on this subject, having been convinced that the lymphoid tissue in the post-nasal space is a fruitful source of systemic infections.

Dr. J. L. Goodale said that while he agreed with Dr. Rice about the use of astringents, such applications were of distinct service in the apparently infectious, though secondary, inflammations of the mucous membrane of the soft palate and uvula.

The So-called Immunizing Treatment of Hay Fever.—Dr. E. Fletcher Ingals of Chicago read this paper, detailing his observations. The fluid extracts of the pollen from golden rod and ragweed were combined in equal proportions and given four times a day, beginning with a dose of two minims and gradually increasing up to twenty minims. The patients were instructed to continue the remedy for a week or two and then stop it if there were no symptoms of hay fever. Twelve patients, or 67 per cent., asserted that they were relieved by the internal use of this preparation. In several instances the hay fever returned on stopping the medicine, but disappeared on resuming it. Thirteen believed they were benefited by using it in spray form. Sixty per cent. of the whole number were subject to asthma during the attack, and half of these reported benefit or entire relief from the asthmatic symptoms, as they believed, from the use of this medicine. In two cases it caused disturbance of digestion, and in one it repeatedly gave rise to menorrhagia and had to be discontinued. The dose used of the fluid extract was less than one-fourth that ordinarily recommended, yet an attempt to increase the dose in many instances seemed to disturb digestion. According to the eclectics, ambrosia is a hæmostatic, and this, perhaps, explained the fact that many of the patients spoke of a dryness of the nasal mucous membrane. If this were found to be the uniform action of this remedy it might prove of value. About 25 per cent. of those benefited by this treatment attributed their hay fever to ragweed, and none to golden rod. It should be remembered that these remedies were used very little in medicine; hence it was not improbable that the preparations employed had been long in stock and were of low efficiency. These sources of error would be eliminated during the coming hay-fever season.

Some Clinical Features Regarding Hay Fever, and Its Rational Treatment.—Dr. George B. Hope of New York read this paper. For several years past, the author said, he had studied carefully hypertrophic conditions of the nose. It was pointed out that the pollen theory of the origin of hay fever had received a severe set-back from the occasional occurrence of cases of perennial congestive activity of the nose. In every instance coming under his observation the clinical symptoms of hay fever had been associated with the middle turbinate hypertrophy, and the surgical treatment of this condition had invariably resulted in benefit, though not always in cure. A snare was used for the ablation of the hypertrophied turbinate tissue.

Dr. John O. Roe of Rochester said he still believed that hay fever was a reflex disorder arising from disease in the nose, quite commonly in the middle turbinate.

Dr. J. N. Mackenzie of Baltimore said that if any benefit had occurred in Dr. Ingal's cases it should be attributed to a psychical effect upon a neurotic individual. It were better these experiments had not been made, for they opened the door to much irregular practice.

Dr. F. I. Knight of Boston preferred to speak of "autumnal catarrh" as more specific than the term hay fever. Such catarrh was recognized as having three important etiological factors, viz., (1) local irritation; (2) local disease and (3) a neurotic tendency. He had seen some relieved by attention to local conditions, but very few cured.

Dr. W. E. Casselberry said that the operation on the middle turbinate was neither a painless nor a bloodless operation, and extreme difficulties had arisen at times from hemorrhage and sepsis. Even with the probe he had not always been able to detect the sensitive areas upon which Dr. Roe laid so much stress.

Report of a Case of Stammering.—Dr. G. Hudson Makuen of Philadelphia reported this case and presented the patient, a man of thirty years, who had stammered severely for twenty-eight years. This man had appeared to have no conception of the time element in speech, and spoke with great rapidity. The organs of speech being unable to meet the demands made upon them, inco-ordination resulted, and the ear soon failed to recognize the defect. The ear of the stammerer, therefore, must be trained to recognize normal speech before he can be taught to use it. So important was this element in the treatment of stammering that certain so-called stammering cures depend entirely upon this. The patients are sometimes taught to beat time with the foot, or by nodding the head, or by the use of the swinging pendulum. The speaker thought that in most cases it was better to try and educate the person to recognize the proper time element without such extraneous and artificial devices. In the case under consideration the treatment consisted in rhythmical exercise of the organs of respiration and phonation, making use of the physiological elements of our language. This served the double purpose of familiarizing the patient with correct forms of speech and training the ear with forms and sequences. The patient came to him last January and remained under treatment two weeks. His father and sister were also stammerers. The patient was taught to beat time with his own respiratory organs, counting one, two, three, four, etc., and each time increasing momentarily the size of the abdomen. He was then taught after the same fashion to speak in syllables.

Changes in the Form of the Arytenoid Cartilage Occasionally Seen in Singers and Actors.—Dr. Clarence C. Rice of New York read this paper. He said that when there was a lesion of the larynx existing alone and independently, it might be stated, as a rule, that it resulted from the use of the voice in an extraordinary trying way. A case was cited in which an actress was compelled to shriek loudly at each nightly performance. Examination showed that the convexity of the proximal surfaces of the arytenoids had been hammered flat. Of course the indication was to change the pitch of vocalization. The overuse of certain groups of laryngeal muscles was apt to be associated with too little use of the other muscles. It was not uncommon to observe a remarkable compensatory increase in the size and function of the false vocal bands in cases of impaired action of the true cords. He knew of a lady singer who successfully retained her position in a choir despite the fact that there was paralysis of the left vocal band. Choked voice from over- or impaired use of the voice was most frequently seen in second-rate singers, and was commonly dependent upon an effort to use the voice either above or below its proper range. For this reason the prognosis was not good.

Dr. S. W. Langmaid of Boston said that often the first symptom was the losing of the high notes, because such undue muscular effort was required that the patient shrunk from using such force.

An Epidemic of Non-suppurative Cervical Adenitis.—Dr. Dr. S. W. Langmaid of Boston made this report. Four cases were reported in which there was an initial chill and a sharp rise of temperature, followed by extreme dysphagia and great debility, with moderate swelling in the throat, and subsequently a rather sudden development of a cervical adenitis. There was no involvement of the larynx in these cases, and hence in this respect they were different from a series reported to this Association by Dr. Glasgow in 1890. The speaker suggested the possibility of these cases being dependent upon the absorption of noxious matter in the region of the tonsil.

Drs. H. L. Swain, G. A. Leland, J. L. Goodale, W. K. Simpson, F. C. Cobb, A. Coolidge and J. W. Farlow all reported having seen similar cases.

The Chemical Pathology of the Saliva and Pharyngeal Secretions (Sialo-Semeiology) as a Means of Diagnosis.—Dr. D. Braden Kyle of Philadelphia read a suggestive paper with this title. The author said that he had studied the composition of the saliva since 1895, and had become convinced that such research rendered valuable aid in diagnosis. His investigations included normal saliva as well as hypoacid and hyperacid saliva. It had been found that the saliva was liable to physiological oscillation in constant relation to the fluids and solids of the body. It was a well-known clinical fact that the saliva from certain persons is exceedingly poisonous, and it is quite probable that some of the reflex diseases, as for example, asthma, might be traced to perverted salivary secretions. In answer to questions, Dr. Kyle said he had taken pains to exclude bacterial action. The saliva in the cases referred to as poisonous was essentially poisonous in its chemical composition, irrespective of any bacteria present. The cause of the foul odor he believed to be hyperacidity of the secretions with the presence of ammonium salts, thus leading to the formation of hydrogen sulphide. He had succeeded in curing certain cases of hay fever by attention to the secretions.

Third Day—Wednesday, May 28.

Syphilitic Contraction of the Pharynx.—Dr. George A Leland of Boston presented a patient showing extensive syphilitic disease of the nose with contraction of the pharynx.

A Case of Incised Wound of the Larynx.—Dr F. E Hopkins of Springfield reported this case

A Case of Foreign Body in the Bronchus.—Dr. Hopkins also reported this case. A young girl, while skating, placed a toy balloon, with reed attachment, in her mouth. It was suddenly drawn down through the larynx into the trachea by inspiration while laughing. The girl's condition had appeared desperate on her arrival at the hospital. She took the anæsthetic badly, and it became necessary to do a tracheotomy hurriedly. The body was found in the right bronchus, and was removed with forceps, the patient seeming at the time to be moribund. However, after the removal of the toy, her recovery was uneventful.

Dr. E. Mayer of New York thought the tracheotomy should be done under local anæsthesia, and then, if necessary, a general anæsthetic could be more safely administered and the exploration proceeded with.

Dr. Price Brown of Toronto, Ont., reported a case in which he had done tracheotomy under general anæsthesia, the dyspnœa and cyanosis passing away under the influence of the anæsthetic. The case being obscure, and the child small, the tube was left in for four days. It was then taken out, whereupon the patient had a fit of coughing and expelled a long grain of corn. Although it had remained so long a time in the respiratory passages, there was no evidence of germination.

Dr. H. L. Swain of New Haven referred to a case in which a child of three months swallowed about half a peanut, which became lodged in the respiratory passages, but gave no definite signs of its presence and exact location. Finally, after five months, the intruder was expelled and, strangely enough, showed no distinct softening.

Dr. D. Bryson Delavan of New York was inclined to think the case reported in the paper was unique in that the foreign body was the largest reported to have been inhaled into the trachea. He looked upon a general anæsthetic as exceedingly dangerous in these cases.

Dr. A. Coolidge, Jr., of Boston, said that when he had reported his case at the Chicago meeting he had stated his belief that the possibility of inspecting the trachea and bronchi by direct illumination took away a great deal of the danger of inhaling such bodies. It was much safer to attempt to remove the foreign body than to leave it there, though a waiting policy was certainly preferable to fishing around blindly in the bronchi with long forceps. The bronchi are very tolerant of foreign bodies, and in a self-possessed adult cocaine anæsthesia was all that was required for the performance of tracheotomy.

Dr. W. Kelly Simpson of New York said that if the foreign body were very small and it was making excursions into the trachea, O'Dwyer's cylindrical foreign body tube would be found an excellent means of favoring the expulsion of the body by coughing.

Dr. Hopkins said that the points made against the use of general anæsthesia were certainly well taken, but he had been forced to use such an anæsthetic because the patient was a nervous and excitable girl. She had held the toy in her mouth with the rubber end downward, and this seemed to explain why so large an object had been drawn through the larynx.

Treatment of Empyema of the Sphenoidal Sinus.—Dr. F. Whitehill Hinkel of Buffalo read this paper. It was based upon an experience of twenty cases, in all of which the diagnosis had been confirmed by the operation.

The pain in the head was uniformly severe, but he had been unable to find any distinct localization of this pain. An occasional symptom was pain in the ears and along the temperoparietal region. Eight cases had presented chronic cough with purulent expectoration. Two cases had complained a good deal of pharyngeal catarrh. The only assurance of the existence of a sphenoidal empyema was the discovery of pus welling up from the ostium or from the sinus when irrigated. He had found polypus associated with disease of this sinus in seven cases. There were no characteristic symptoms of disease of the sphenoidal sinus. His experience with irrigation of the sphenoidal sinus through the natural opening had not been satisfactory, as he had not been able in this way to relieve the symptoms and control the empyema, and the irrigation often gave rise to headache. The anterior wall should be broken down with a sharp spoon. The method of approach through the maxillary sinus presented serious difficulties. After a free opening of the anterior wall of the sphenoidal sinus, he had observed one case of severe secondary hemorrhage occurring ten days subsequent to the operation. This hemorrhage he attributed to injury of the sphenopalatine artery at the operation. Comparatively few such cases of hemorrhage had been reported.

Dr. J. H. Bryan of Washington, D. C., commented upon the anatomical variations met with, and declared that no two sphenoids that he had examined were alike. The dangerous character of this region had been alluded to in the paper. The carotid artery runs very near by, and if a larger piece of bone than intended were detached there was great danger of injuring this blood vessel, or of opening the orbital cavity and producing an orbital abscess. The treatment of these cases was difficult.

Dr. E. Mayer said that he thought he had discovered a new factor in the etiology of sinus affections, *i. e.* automobile riding. The rapid motion of the air apparently forces disease germs into the accessory sinuses.

Dr. W. E. Casselberry called attention to the association of syphilis with suppuration in the maxillary, ethmoidal and sphenoidal sinuses.

Dr. J. W. Farlow reported an interesting case of empyema of the sphenoidal sinus. By the use of the Grünwald wedge-shaped hook a large opening could be secured, and the sinus curetted and explored.

Dr. D. Bryson Delavan emphasized the remark made by Dr. Casselberry by stating that he had, in several of his own cases, secured almost perfect results without opertion simply by administering the iodides to combat an underlying syphilitic taint.

Dr. Hinkel said that he had never relieved any of his cases of sinus empyema by antisyphilitic medication. The association of dull pain in the eye with hemicrania was an important point in the symptomatology.

Adenoma of the Nose.—Dr. E. Mayer of New York reported a case of this kind in which he had removed a papillo-adenoma weighing 117 grams. It had caused extensive absorption of bone.

The Use of Rubber Splints in the Treatment of Curvature of the Triangular Cartilage.—Dr. Price Brown of Toronto read this paper. He said that he preferred to have a tight fit, in order that the splint may be kept in place by elastic pressure. As a rule, the splint should not be removed until solid healing had taken place, whether this was two or four weeks. However, the patient should be seen daily at first, and the passages cleansed. This prolonged retention of the rubber splint had not given rise to sepsis. In one case the splint had been worn eleven weeks without untoward result.

Leukoplakia.—Dr. Frederic C. Cobb of Boston presented this paper. He said that by the early writers this condition had been described as ichthyosis. The red vulcanite toothplates seemed to be a cause when associated with an individual predisposition. Out of sixty-eight cases of non-syphilitic leukoplakia 98.4 per cent. occurred in smokers. The greater frequency of the disease in the male sex had been ascribed to smoking, yet the disease had not been seen among Turkish women who are known to be excessive smokers. In a very large proportion of the cases there was a syphilitic history. The usual termination of leukoplakia was in carcinoma. During the last five years there had been ten cases of leukoplakia at the Massachusetts General Hospital. Eight of these were males, all smokers, and the average age was a little over fifty years. In one case the disease had existed for twenty-three years before the development of carcinoma. Only three of the patients admitted syphilitic infection. Four of the cases were on the tongue.

A New Operation for the Restoration of the Nasal Septum.—Dr. John O. Roe of Rochester read this paper. He dissects up sufficient tissue from the under side of the lip to fill the deficiency of the septum. The upper lip is buttonholed and the flap pushed through the buttonhole at the point of insertion of the lower columnar. By pulling this flap inward and stitching the cut surfaces together, and then to the anterior stump of the septum, a very excellent substitute for the original septum is formed. In the case reported no scar was left where the flap was put through the lip.

Officers Elected.—*President*, Dr. J. H Bryan of Washington, D. C.; *First Vice-President*, Dr. George A. Leland of Boston; *Second Vice-President*, Dr. T. Melville Hardie of Chicago; *Secretary and Treasurer*, Dr. J. E. Newcomb of New York; *Member of Council*, Dr. J. W. Farlow of Boston.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held May 6, 1902

Joseph Collins, M.D., President.

A Case of Primary Myopathy.—Dr. J. Ramsey Hunt presented a girl of sixteen having a negative family history. One year and a half ago there was noticed a difficulty in pronouncing words, and also a nasal twang. A few months later there was some regurgitation through the nose, and it was noted that she did not close the eyes completely during sleep. Examination showed marked deficiency of the muscles of the face, on voluntary and emotional innervation. The orbicularis oris and the orbicularis palpebrarum and the zygomatici were chiefly affected. The palatal muscles were motionless. The muscles of the upper arm and shoulder were small. The tendon reflexes were active, but there was no evidence of involvement of the pyramidal tract. The speech mechanism was easily fatigued, articulation becoming less distinct on prolonged effort.

Tumor of the Brain.—Dr. Max Mailhouse of New Haven presented a brain taken from a woman, who had been admitted to the New Haven Hospital on March 13, with a history of severe headaches for a year and a half, and considerable mental disturbance. Speech was incoherent and muttering. There were exaggerated knee-jerks; also ankle clonus and increased plantar reflexes. The optic nerves were atrophied and she could only distinguish light. Twitching of the muscles of the eyebrows was observed the first night, and she was so restless as to require restraint. During the six weeks she was in the hospital there were two or three attacks of vomiting. She complained constantly of headache and thirst. On April 14, when examined by Dr. Mailhouse, there was slight strabismus from weakness of the left internal rectus; the knee-jerks were exaggerated and there was ankle clonus on both sides. There was loss of vision. She was mentally tolerably clear. She became more restless and talkative, and the pulse more rapid and irregular, and two days before death she became unconscious and died in this condition. The autopsy was made on the day after death. It revealed a tumor in the interpeduncular space, and examination of the tumor made it appear that the growth either originated in or soon involved the optic chiasm. The tumor pressed upon the left third nerve and also upon the facial tracts above the pons, causing the spasmodic twitching of the facial muscles. No report of the microscopical examination had yet been received.

Paralysis of the Serratus Magnus.—Drs. Joseph Collins and I. Abrahamson presented a woman of twenty-eight, who had been in fair health up to last November. At this time she had had an attack of suppurative tonsillitis, which was followed by suppuration of the glands at the posterior border of the sternomastoid muscle. These were incised and much pus evacuated. About seven weeks afterward the shoulder was noticed to project upward, and it was the seat of a throbbing pain. When seen, the left scapula presented a winglike appearance, and what appeared to be an isolated paralysis of the serratus magnus muscle. Some of the fibers of the supraspinatus and of the infraspinatus showed slight reaction to the faradic current and some slight atrophy. There was a larger linear post-operative scar along the upper posterior border of the sternomastoid muscle. There was some enlargement of the glands on the left side of the neck. The diagnosis was based upon the position of the scapula while at rest, on the peculiar limitation of movement when the arm was brought forward at a right angle, on the absence of sensory disturbances and of symptoms pointing to spinal origin and to the presence of degeneration reaction. The lesion was evidently a post-infectious neuritis involving the posterior thoracic nerve, probably that portion in the body of the scalenus. The chief features of interest were: its peculiar etiology; its occurrence in a female; the absence of trauma and of any of the ordinary causes; its late recognition; the change in the position of the scapula when at rest; the presence of scoliosis, as had been observed by Stromyer in a few cases.

Dr. W. M. Leszynsky said that most of these cases of serratus magnus paralysis were due to pressure or to progressive dystrophy, but he had shown a case to this society in which it had followed an infection—a pneumonia.

Atypical Syringomyelia.—Dr. Joseph Collins showed a case which he had diagnosticated as one of syringomyelia. The patient was a stationary engineer, fifty-seven years old, who had lived a temperate and healthy life, not exposed to syphilitic or inorganic poisons. Three years ago he noticed, on going downstairs, that he tripped easily, and that he was getting clumsy in the use of his feet. About the same time he remarked that the little and ring fingers of both hands were becoming stiff, as he termed it. He found difficulty in using these fingers dexterously, and in appreciating objects that came in contact with them. Soon these fingers became deformed, a flexor deformity of the second and third phalanges, which was gradually progressive, and which was dependent upon atrophy of the hypothenar muscles and the last interossei. At the same time the loss of sensibility in the ulnar distribution progressed. About a year ago a slight sore developed on the ball of the right foot, now a typical perforating ulcer. The patient presented now the following: (1) Atrophy of the hypothenar and last interossei muscles, and consequent deformity; (2) Glossiness of the skin of the hands; (3) Analgesia and thermoanæsthesia, and partial tactile anæsthesia in the little fingers and the ulnar halves of the ring finger; (4) Thickening of the ulnar nerves, rendering them palpable; (5) Increase of mechanical irritability of the muscles of the upper extremities; (6) Typical perforating ulcer on the ball of the right foot; (7) Analgesia and thermoanæsthesia of the toes and the outer half of both feet; (8) Slight exaggeration of the tendon jerks in the lower extremity; (9) No deformity of the spine and no symptoms referable to the cranial nerves; (10) No disturbance of the sphincters or of the sexual function. Dr. Collins said the case was not a typical one of syringomyelia, but that diagnosis seemed more likely than any other. The condition was a progressive one.

A Case of Raynaud's Disease.—Dr. B. Onuf presented a young man with Raynaud's disease that had existed for about two years. Sensation was normal during the attacks. There was a history of rheumatism of the joints. He was a sailmaker by occupation, and in his work the tool used caused pressure on the right palm. The urine showed an abundant deposit of urates. He had not been improved by any method of treatment so far employed.

Mental Dissociation in Depressive Delusional States.—Dr. Ira Van Gieson was the author of this paper, which, he said, represented some of the work formerly done in the New York Pathological Institute. The subject of the report was a Russian of twenty-six, having a good family history. In February, 1900, he had begun to suffer from insomnia, headaches, and loss of appetite, and had become despondent. The general health had rapidly deteriorated, and a local physician, on examining him, stated that his trouble was largely indigestion, and that there were "lumps" in the bowels. This was the foundation of a delusion which the patient fondly cherished. There was also a belief that there were worms in the intestine, which worked upon the lumps and broke them up into minor lumps, and sent the latter throughout the body. The patient believed that he was rescued from his dire distress by three agencies, viz., the spleen, the soul, and the veins, the soul being the scavenger and the spleen the director. When the attention of the soul was distracted this work was not well done. As might be expected the patient was extremely depressed, and his physical condition suffered. He could speak readily only on the all-pervading subject of his delusion. The loss of attention was marked, except as regards the systematized delusion. No gross motor disturbances were present. The patient reacted slowly to external stimuli. There were no sensory disturbances, no hallucinations, and no tendency to self-destruction. He could fully realize his environment and his relations to space and time. As soon as he passed into hypnotic trance a metamorphosis almost instantly occurred, the patient passing from intense depression to a state of great exaltation. Despite this the focal delusion persisted, and appeared to be far better organized. This clearly pointed to the fact that either the state of depression was one of secondary formation or the delusion, being secondary in its origin, had gained sufficient strength to stand by itself, even after the emotional basis had been withdrawn. The latter alternative seemed to be the more probable. In his trance he could vividly remember all that had taken place in his waking life, and, on the other hand, he could recall fairly well what happened while in the trance. Later on the patient, at one time, passed into a deeper trance, and then passed from a state of inexpressible delight to one of grave composure. In the last trance personality he could remember all the experiences of the other trance personality and of the waking personality. The relation of these three personalities was described diagramatically by three concentric rings. The central one was the melancholic personality, and outside of this were successively the rings representing the first and second trance personalities. Of the three personalities, the waking was pathological. The first trance personality was an exaltant, while the second trance personality approached closely to the patient's healthy condition. The course of these personalities resembled quite closely what was observed in circular insanity. These alternating personalities were, however, ephemeral. Soon the first personality shrunk and finally disappeared altogether. In the course of time the first trance personality disappeared, and never returned. The mood of the second trance personality then lost some of its former seriousness. The tendency was for the intermediate personalities to disappear and the last one to become the dominant one. The process of evolution of species in general was one great illustration of the process just described. Throughout all of these transformations the central delusion remained unshaken. The great assimilating power of this delusion was wonderful. Various suggestions were given to this patient; although they were designed to break up the nucleus of the delusion, they were turned about by the patient and fed into this systematized delusion. It was necessary to follow the patient in his delusion and play into the hands of the latter in order to make the suggestion take root. Direct suggestion during deep hypnosis was the usual method of breaking such a strong delusion, but the objection to this method was that it was apt to be only temporary in its effect. The method of emotional substitution was especially valuable in a case of this kind. Some unimportant sensory changes were first attempted, as for example, the abolition of the unpleasant thermal changes in the "lumps," but they were only partially successful. The effort was then made to fuse the different personalities. During hypnosis dreams were suggested to the patient with the object of effecting changes in the central delusion. For example, in one of these dreams his father told him that these lumps would go away. These dreams impressed him deeply though slowly. When the good dreams had become dominant the spleen and soul began to drop out, and then the galvanic current was substituted for the soul with great benefit. Small spots were next substituted for the large lumps. The spots were gradually confined to certain definite areas instead of being vaguely disseminated. The patient's melancholia disappeared completely, and he had now resumed his original vocation. The case was regarded as a triumph for this mode of treatment, and as a type of many other cases now in the State Hospitals for the Insane.

Dr. Mary Putnam Jacobi asked whether the transition of the two personalities had occurred spontaneously or had been brought about by some special manœuvre.

Dr. Henry Rafel asked if there was any other case on record in which hypochondriasis had been cured in this manner by hypnosis.

Dr. Van Gieson said that the paper had been prepared by his former associates at the State Pathological Institute. The transition of the personalities had occurred spontaneously. He was not sufficiently familiar with the literature to answer positively the second question. If hypnosis had been used in the ordinary way the result would have been only transient benefit; a permanent cure had been effected by a thorough understanding of the whole mechanism of hypnosis. This patient had been cured eighteen months ago.

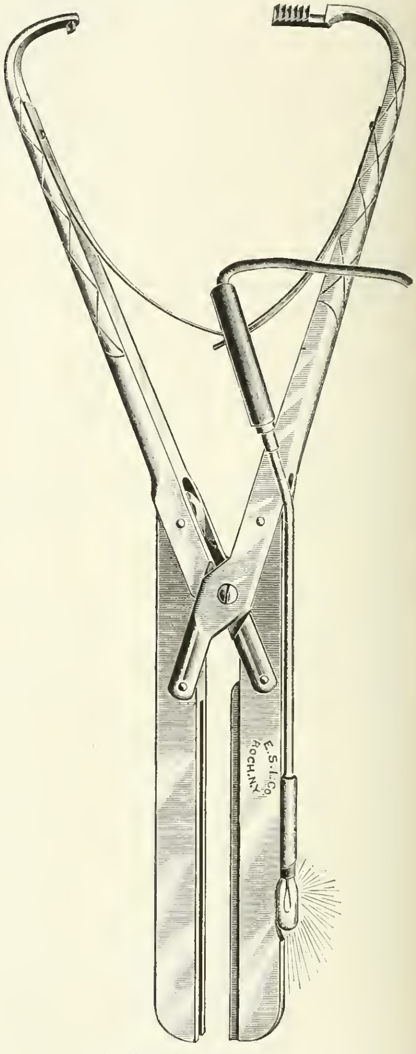
On the Indications for Reduction Cures.—Carl von Noorden says positively that a reduction cure begun on proper indications never deserves the name of a "weakening cure," provided that the choice of procedure, the rapidity with which it is carried out, and the amount of weight lost are arranged to suit each individual case. Before entering into the treatment of an obese patient, it becomes necessary, above all, to decide the question whether an actual reduction cure is indicated, or whether the treatment should be restricted to the prevention of further fat deposit, and to the removal of dangerous and disturbing complications. Above all, we must avoid making an idol of this or that method—so large is the choice of methods at our disposal, both as regards physical aids, and, more especially, dietetic prescriptions, that each individual case can be reckoned with. In many cases it is undoubtedly of no consequence which method is chosen—it can be left to the wishes of the patient and to external conditions. In other cases, however, not only practicability and success, but also health and life, depend upon a proper choice.—*International Medical Magazine.*

New Instruments.

CLAMP FOR ATTRITION OF THE BROAD LIGAMENTS.

By S. H. LINN, M.D.,
ROCHESTER, N. Y.

Dr. E. Doyen of Paris, France, was the first, I believe, to use an angiotribe in hysterectomy, but he acknowledged that with his instrument the crushing must be carefully limited in order to avoid dividing the broad ligament. This disadvantage is completely eliminated in the progressive pressure clamp or angiotribe here illustrated, which, by means of a slot and ridge extending the entire length of the blades, reduces the tissue to a thin cellulo-fibrous layer without rupturing the external tunica.



The clamp is twenty-nine centimeters long, the blades which are non-crossing being twelve centimeters by two and one-half centimeters, and weight only 350 grams. The handles are separated by two springs and are under the control of an automatic rachet. As pressure is exerted on the handles the crushing force is augmented until the maximum point is reached, when the blades separate automatically, the force of the compression being equal throughout their entire length.

This instrument also possesses another novel feature in that it is electrically lighted, enabling the surgeon to positively ascertain the nature of the tissues he is compressing. The attachment for the lamp, which is on the upper edge of one blade, only adds one-fourth of a centimeter to its width. The lamp is of unique design and marks a new era in the electrical lighting of hidden cavities, as it gives a most brilliant white light and is practically cold, it is durable and easily detachable.

The powerful crushing force of this instrument enables one to reduce the tissue of their peritoneal lamina, thus avoiding large ligamentary stumps, the tardy absorption of which sometimes causes infection. The attrition is sufficient for definitive hemostasis, although some prefer to ligate before cutting. In making ligations this previous crushing is advantageous, as it allows the use of very fine silk ligatures, which are non-irritating and prevent the evolution of small purulent or inflammatory foci. It also obviates all danger of the ligature loosening and the infected pedicle mounting higher and causing mortal infectious symptoms.

When it is desired to leave forceps *in situ* this instrument permits the use of a smaller forceps, which is less irritating, and also prevents the danger of secondary hemorrhage. Cicatrization is more rapid and the elimination of mortified parts takes place sooner.

The clamp may be applied upon the broad ligament as soon as it becomes accessible, thus enabling the surgeon to detach it by tearing away from the cervix uteri much higher than formerly.

The Linn clamp is manufactured by The Electro-Surgical Instrument Co., Rochester, N. Y.

Spasmodic Wryneck Appearing in the Course of a Case of Exophthalmic Goiter.—Walter S. Stern reports the case of a girl of fourteen years in whom wryneck had developed during the course of exophthalmic goiter. The youth of the patient is unusual for both affections. Out of thirty-two cases of wryneck Walton reports only two cases under twenty years of age. In the differential diagnosis tubercular spondylitis can be excluded because the chin, though deviating to the right, looks upward. Other symptoms which serve to exclude Pott's disease, are that the pain is not constant nor localized, there is no limitation of motion of atlas or axis, no swelling of the bodies of the vertebræ, no retropharyngeal abscess, etc. From congenital torticollis the history, the symmetry of the head, and the absence of any permanent contractures, as shown under anæsthesia, give the differential diagnosis. From scoliosis or congenital elevation of the shoulders, the presence of the various contracted muscles speak for wryneck. In this case the author would follow out the treatment applicable to exophthalmic goiter.—*The Cleveland Medical Journal.*

The Lingual Tonsil.—Henry B. Lemere says that the trouble resulting from the enlargement of the lingual tonsil is one of adult life, and essentially of neurasthenics and of women. The symptoms are vague, consisting sometimes of weariness of the throat, recurring attacks of laryngitis, a nervous cough, the feeling of a foreign body in the throat, or indefinite pain. It is extremely bad practice to name the complaint globus hystericus, or paresthesia of the pharynx, without examining to see whether there be any lesion of the throat. Treatment consists in removal of the enlarged tonsil. The author finds the lingual tonsillotome the most useful in this operation. The application of cocaine makes it entirely painless.—*Medicine.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending July 12, 1902:

	Cases.	Deaths.
Measles	230	8
Diphtheria and croup	283	36
Scarlet fever	178	16
Smallpox	28	9
Varicella	21	..
Tuberculosis	245	160
Typhoid fever	64	13
Cerebro-spinal meningitis	..	9

Sciatic Neuritis and Its Treatment.—L. Harrison Mettler says that for the present we may assert that all appearances warrant the conclusion that sciatica is a neuritis of the sciatic nerve, that so-called secondary sciatica is not, in the strict sense, any affection of the nerve at all, and that there is but one positively known form of sciatica, namely, sciatica neuritis. In the treatment, the methods that afford the highest degree of success are more or less identical with those that prove to be most efficacious in the management of neuritis. Counter-irritation and the actual cautery even, the internal administration of vasomotor sedatives, the free use of cathartics, diuretics and diaphoretics, are the chief measures depended upon in the subacute and acute stage. Analgesics, narcotics, and sensory depressants produce less permanent results in sciatica than they do in other forms of neuralgia. In the acute stage, general and absolute rest, even to the point of strapping the limb if necessary, is *sine qua non.* Opium, aconite, belladonna, etc., are all useful. After the trouble has become chronic, the author resorts to the steady use of strychnine, preferably by the subcutaneous method, in doses of from 1-70 to 1-20 grain twice a day. Massage, baths, and the steady use of mild currents of electricity should be applied every day.—*The Therapeutic Gazette.*

The Permeability of the Kidney in Health and Disease.—W. E. Wynter describes the phloridzin test and the methylene blue test for determining the functional activity of the kidney. A more recondite means of estimating renal insufficiency is by determining the freezing point of the blood. Koranyi, the originator of this method, found a lowering of the freezing point of the blood in nephritis, tumor, hydro- and pyonephrosis, and also in animals upon the ligation of both ureters. Of practical significance is the observation that no change of the freezing point of the blood follows when one kidney remains, an observation which harmonizes with clinical experience of the rapidity with which the remaining kidney compensates for the loss of its fellow. For practical purposes it may be concluded that a lowering of the freezing point of the blood to 0.58° C. or beyond, signifies insufficiency of the kidneys, and operative interference should not follow until the freezing point is about 0.56° C. A freezing point of the urine higher than 0.9° C. is an index of insufficiency of the kidneys, but of most significance would be the freezing point of the segregated urines respectively.—*Treatment.*

Idiopathic or Congenital Hereditary and Family Hæmaturia.—Leonard G. Guthrie has knowledge of the existence of idiopathic hæmaturia in twelve persons. The characteristics of the disease may be thus summarized: (1) It is hereditary, familial, and congenital; (2) The hæmaturia may be presistent for many years but vary in extent. In some cases it may cease for a time, but in all it is apt to recur, or to increase, in paroxysmal attacks or in exacerbations. The blood casts show that the hemorrhage is from the substance and not from the pelvis of the kidney. The amount of blood passed during exacerbations is much greater than is ever seen in cases of nephritis; (3) The paroxysmal exacerbations are usually accompanied by slight pyrexia, headache, malaise, vomiting, and slight pains in the back or limbs; (4) Idiopathic hæmaturia is not associated with œdema nor with ascites, nor with the cardiovascular changes following ordinary nephritis; (5) The hemorrhage is not due to the presence of uric acid nor of oxalates; (6) The specific gravity of the urine is not unduly low. It varies from 1015 to 1030. Finally none of the subjects of idiopathic hæmaturia is a "bleeder." The author describes several cases.—*Medical Press and Circular.*

The Indian Method of Using Nux Vomica in Dyspepsia.—Hem Chandra Sen prefers nux vomica in powdered form, as it remains in the alimentary tract for a long time and thus allows gradual absorption of its active principles, and a prolonged, mild, stimulating action on the secreting cells and nervous mechanism of the alimentary tract. One of the best Indian methods of preparing nux vomica in powdered form for medicinal purposes is to boil it in milk or a mixture of equal parts of milk and water. When the seeds become soft from prolonged heating, the cotyledons are scraped apart and the embryo is removed. These scraped cotyledons are then converted into a fine paste. As soon as the cotyledons show a tendency to become hard they are boiled again, to render them soft for easy manipulation. The process of boiling in milk is said to have a mitigating effect on the nux vomica. It is a very important point to remember that the efficacy of nux vomica, like that of arsenic, is enhanced if the patient takes a sufficient quantity of milk, ghee or butter. This preparation of nux vomica can be used with safety for a long time.—*Indian Medical Record.*

Conservatism in the Treatment of Inflammatory Affections of the Uterine Adnexa.—Hugo Ehrenfest makes a plea for conservative surgical methods, not because he fears the operation, but because the remote results of either conservative or radical interference are admittedly excellent, but not wholly satisfactory. He does not feel justified in promising a patient suffering from pus tubes that subsequent to operation she will be positively free from further trouble. Operated patients—just as well as those treated or cured by conservative methods—must face the possibility of trouble due to the residua of repeated attacks of pelvic peritonitis, especially intestinal adhesions. In suppurative cases conservative nonoperative treatment should be given a trial, unless definite symptoms make operation imperative. The results of conservative treatment are better among the well-to-do than among the working class, where, indeed, they are very unsatisfactory. If an operation becomes necessary, radical operation will be the operation of choice, vaginal drainage the method of necessity.—*St. Louis Medical Review.*

Intentional Post-Hemiplegic Tremor.—D. de Concilis concludes from his study of the subject that in cases of intentional tremor or ataxia following hemiplegia of cerebral origin there is a lesion of the motor pyramidal tracts. In cases complicated by choreiform movements this supposition would explain facts which have heretofore not been understood. Even in cases where the tremor and the ataxia do not represent a post-hemiplegic disorder nor a symptom of multiple sclerosis, no other microscopic lesion of the central nervous system is to be found, but there is a constant lesion of the motor pyramidal tract, and we may, therefore, admit that intentional tremor or ataxia are due to a lesion of this tract and to the partial and irregular destruction and stimulation of single fibers of the same.—*Annali di Medicina Navale.*

Two Intestinal Toxins.—From the results of his experimentation, J. Le Calvé concludes that indol and probably skatol cause congestive changes in the nerve centers, leading to hemorrhages, or to œdematous infiltrations, with consequent defective coloration of the neurones and neuroglia. The kidneys are the seat of congestion, the liver, lungs, and spleen of intense hyperæmia. The intestinal toxins also determine peripheral œdemas. The action of the toxin seems to depend upon its influence on the vasomotor centers. Under ordinary conditions indol and skatol appear to act as a physiological rather than toxic agents; cold increases the vasomotor action. Hot baths (113% F.) constitute the best treatment for intoxication by these substances, by stimulating vasomotor action and increasing diuresis and the oxidation of excretory products, thus dissipating intoxication and causing a retrogression of the structural degenerative changes.—*Archives Générales de Médecine.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health, and U. S Marine Hospital Service, during the week ended July 12, 1902:

TYPHOID FEVER FROM SOURCES OTHER THAN WATER SUPPLY.*

By M. A. VEEDER, M.D.,
LYONS, N. Y.

THAT typhoid fever is at times waterborne has been demonstrated beyond a reasonable doubt. Indeed the evidence to this effect is so plain that it tends to fill the mind to the exclusion of every other idea on the subject. And so it has come to pass, during the Spanish-American and South African wars, that sanitarians have experienced something very like a rude awakening. The waterborne origin of typhoid fever seemed so complete an explanation, and so well established that it was with evident elation, and almost gayety, that the task of ridding the armies of the scourge was entered upon. A few filters, a little boiling, and here and there a conduit to bring water from sources beyond the possibility of contamination, and the whole difficulty ought to disappear. But instead of disappearing it became absolutely enormous. And then there was talk about raw recruits and American and British soldiers, the most intelligent in the world, were credited with utter lack of common sense, and willingness to obey orders. No longer ago than February of the present year I met with a communication to this effect, published by a medical officer of health in South Africa, in which it was charged that the prevalence of typhoid in the locality was due solely to the ignorance and wilfulness of the soldiers in using bad water in preference to that known to be good. It is conceivable that there might be carelessness on the part of a few individuals even in the presence of an epidemic of hundreds of cases of disease, but that there should be prolonged continuance of such wholesale neglect of ordinary precautions as would be necessary to create an epidemic of such dimensions is inconceivable. Even if the men were heedless their officers surely would have insisted upon observance of the precautions which they understood to be necessary. As a matter of fact, there are plenty of reports of instances in which every possible precaution in reference to water supply was taken, and yet typhoid continued to spread as though nothing had been done. This sort of thing is most apt to occur in camps, typhoid being preeminently the camp fever, but it is met with also in civil life. The question as to typhoid from sources other than water supply concerns those living in cities and villages, as well as in isolated country residences, or camps in the woods.

The history of the typhoid bacillus planted and living in ordinary garden earth is a chapter as yet almost wholly unwritten. Whether it subsists in the soil directly, or finds a host in some worm, or living organism, or in some product of decomposition I do not know, but somehow it survives in the ground just as successfully, or even more so, than it does in water. The evidence of its presence either in soil or water is very much the same. The bacillus itself cannot readily be found in either case, but in each instance there is a history of exposure to contamination that is perfectly definite and tangible, and there follows origination of cases plainly due to such contamination. Such observations as the writer has been able to make lead irresistibly to the conclusion that the burial of typhoid material in the earth, without adequate disinfection, is the surest way of perpetuating the disease in any given locality, keeping it alive from year to year, and causing it to become endemic. This procedure is far more effectual in perpetuating the disease locally than is mixing these excretions with water, which does tend at least to get rid of them from the immediate vicinity by carrying them elsewhere—large cities, for example, freeing themselves at the expense of their neighbors down stream—which ought not to be, and which could be avoided, if only we thought so, and would take the requisite precautions, as will appear in the further course of the discussion.

In the case of the typhoid bacillus planted in the soil, there are not likely to be any sensational developments in neighboring towns such as occur when it is carried by water. Its sphere of activity is more strictly localized, but is none the less serious for those directly concerned. And yet, in almost every town and village, some physician or nurse may be found who insists upon the burial of typhoid excretions as the proper method for their disposal, and this, too, was the army method uniformly practiced not so very long ago. There has long been a vague idea that fresh earth is a disinfectant, just as running water has been supposed to purify itself. But there is good evidence that the typhoid bacillus grows to the surface in a mixture of soil and fecal matter, like a fungus in a hot bed, so that burial is no protection whatever against its spread from the surface in a variety of ways that remain to be explained. It is true that the nitrifying organisms of the soil appear to be able to destroy the typhoid bacillus under the particular set of conditions existing in connection with the process known as intermittent filtration, although even this is not yet quite certain. Under other conditions, however, the typhoid bacillus appears to resist the nitrifying organisms as successfully as does the bacillus of tetanus, whose natural habitat is the soil. Indeed, there is evidence that the typhoid bacillus is made to thrive more luxuriantly in the presence of the decomposition processes which originate nitrites and nitrates in soil and water.

And so it comes to pass that there are localities in which typhoid fever is perpetuated from year to year because of soil contamination primarily. In these cases, if there is any contamination of water supply, or wells, it is secondary to that of the soil, and the disease may be spread from the soil itself without the aid of water in ways that will shortly appear. A notable instance of the kind, which came under the observation of the writer, was in the case of a hamlet having a population of perhaps two hundred persons, among whom there were numerous cases of typhoid fever each year for many years in succession, the disease then suddenly ceasing to occur at all. The question of water supply was carefully considered, but there were scarcely any wells used in common, and none so situated as to be liable even to accidental contamination, to say nothing of contamination capable of originating such a persistent epidemic year after year. Nor did there appear to be any specially unsanitary condition of closets and the like. Through their long experience with sickness, the people had come to be unusually cleanly and careful, and it would be hard to find a village neater than the one in question, and yet they continued to sicken and die. As it turned out, the very thoroughness of their efforts was the means of their undoing. It seems that a physician, who was very popular in the community, having attended a large proportion of them successfully through typhoid fever, was accustomed to regard fresh earth as the best disinfectant, and to insist upon their digging trenches and burying typhoid excretions at a distance, from wells especially. It seemed a very plausible idea, and was acquiesced in by the community generally, and especially by a motherly nurse woman, who had become well nigh a professional attending typhoid cases. Eventually the doctor lost his own life through typhoid fever, and so did the nurse, and her son; her husband also nearly died of the disease, and that ended it. With these deaths the custom of burying typhoid material as a means of disinfection ceased, and the disease took its departure, not more than one or two sporadic cases, evidently imported from out of town and not spreading, having occurred in the ten years or more that have since elapsed.

---

*Read before the Syracuse Academy of Medicine.

It was this epidemic, so formidable in proportion to the number of the population, and so extraordinarily persistent, and yet terminating so abruptly, that first suggested to the mind of the writer the desirability of revising, and supplementing existing knowledge in regard to the sanitation of typhoid fever. As it has turned out, instances of the sort just described are very much more common than might be supposed. One recently came under the observation of the writer that is specially instructive. In this instance there were several cases of typhoid in two families that were closely related and constantly visiting each other. The first of these cases was evidently imported from out of town, the others being contracted from it, with great promptitude, in the course of a few days, without the possibility of any interposition of infection of water-supply, the medium of infection in this instance being flies, as will be explained later. Upon the premises occupied by one of these families there was no water-closet whatever, they being accustomed to bury all excretions and refuse in the ground. Nor was there any well on the premises, they getting their water from neighbors, who at no time had the disease. Recognizing the danger of such disposal of typhoid material, a special effort was made to discover and disinfect the parts of the garden where it had been deposited. This proved to be a difficult task, because of promiscuous scattering among bushes and weeds, so that the great liability of missing some of it was commented upon at the time. As the result of these and other precautions, there were no additional cases that year. The next year, however, an individual, who had become an inmate of the household where the excretions were buried in the manner described, contracted the disease, and was the only person so doing in the entire town that year. This person used water for drinking that at no time, either the first or second year, appeared capable of communicating the disease, the source of supply also being such that there could be no contamination secondary to that of the soil. Interpreted in the light of other cases of similar character, encountered during the long epidemic mentioned, and at other times, the conclusion was reached positively that conveyance by water had nothing whatever to do with the origination of this curiously isolated case of typhoid occurring on premises known to have been strongly infected the year before. Infection from the soil may find access to the intestinal tract in many ways other than through the agency of water.

Vegetables that are eaten raw, such as radishes, lettuce and celery, if insufficiently cleansed, will surely convey the bacillus from soil that has been contaminated to the stomach. Garden produce from such sources is to be looked upon with suspicion.

So, too, dust blown by the wind may convey typhoid infection. In the very instance under consideration the soil infected was sandy, so that only a period of drouth and a brisk wind would be required to set it flying over articles of food and drink in the house adjacent. How much dessication the typhoid bacillus will survive I do not think is known, but it would seem to be a subject very much more desirable to experiment with in the laboratory than in kitchen and dining-room.

Still another method of conveyance of such infection is through visitation of flies. The soil of that typhoid bespattered backyard certainly was exceedingly attractive to diptera of various species for some reason. One sultry morning I found them carrying on an investigation, apparently, in reference to the location of certain trenches which I knew to have been there, and, in the midst of their labors, refreshing themselves by frequent visits to a pitcher of milk on the doorstep. If there were pathogenic bacteria growing to the surface anywhere in that garden they would have been in that milk within about thirty seconds.

Growing to the surface is precisely the thing that happens to typhoid bacilli in the soil, even at the end of so long a period as a year, and once at the surface conveyance to the stomach is possible in a great variety of ways.

If typhoid trenches a year old are still dangerous, those that are fresh are still more so. As compared with roundabout processes of conveyance of infection through the intermediary of contamination of soil and water, the carrying of absolutely fresh typhoid material by flies is as deadly as a Gatling gun. Go with me to an ordinary eating-house, where, as it so happens, they have a case of typhoid. Being asked as to the character of the stools, they say that they have saved them all, kept over night without a particle of disinfection, and fairly swarming with flies, within less than a rod of the kitchen door, standing wide open. Is there any wonder that there was a fusilade of typhoid cases among the patrons of that eating-house? The only wonder is that any of them got out of it alive. In like manner in a camp particles of white dust were noticed on some of the food. It proved to be lime brought from the sinks on flies' feet, to which also it was seen sticking fast, thus affording ocular demonstration that they had been walking over fresh excrement and food in the closest possible proximity.

Contamination of food under these conditions is exceedingly rapid and positive. I heard a surgeon in the Spanish-American war narrate his experience in this regard, which had been quite a puzzle to him at the time. In his regiment typhoid fever first appeared in a company composed of the very best and most intelligent men. It seemed strange that those who were most careful should suffer sooner and more severely than others, who took almost no precaution, and yet the explanation was very simple. These kind-hearted and intelligent men did not permit their comrades, on being affected with diarrhœa, to go away to the sinks, which were at a considerable distance. In order to avoid exposure and inconvenience on the part of those who were ill, they provided buckets, which were used in the tents, and emptied at frequent intervals. Thus, unwittingly, instant infection of almost every article of food and drink in and about the tents was made certain through the agency of flies, and the disease gained a tremendous foothold in the very part of the regiment that one would suppose ought to have been most free from it.

Right here attention should be called to a phase of the subject that concerns especially large cities, in these days of trolley lines and one-day excursions and picnics. From the point of view of the present discussion, the closet arrangements at many picnic grounds are little less than murderous. Some time since I learned of a number of cases of typhoid originating at such a place, and had the curiosity to visit it. Fortunately, it was a sultry day, and there were many excursionists from various localities, with their baskets of provisions, enjoying an outing, so that it was possible to see the whole thing in operation. There did not appear to be anything wrong with the water supply, which was from driven wells in a part of the grove remote from any possible contamination. Moreover, many of the excursionists brought with them bottles of cold tea and coffee. And yet of such people, not otherwise associated, and from different towns, there were known to be six who came down with typhoid fever in such manner as to indicate that it was contracted the same day on these grounds. How many there were on other days, and from other places, is unknown, but, even if there were no more, it was sufficiently serious. The explanation of it all proved to be extremely simple. Murderous is just the word to characterize the closet arrangements, they were all open, and right on top of the ground, and in an exceedingly foul condition, without one particle of disinfection, and swarming with flies. The finest part of the grove happened to be in close proximity to these closets, and there were rustic tables, and seats very prettily arranged, and plenty of flies fresh from dabbling in the vilest filth, at the very point at which the excursionists most frequently stopped to eat their lunches. Under such conditions it would require only a case of walking typhoid to start an epidemic, and there was no doubt that such typhoid cases had been on those grounds and used those closets.

Nor is it necessary to go away to camps and picnic grounds in the woods, where arrangements are temporary and imperfect, and where there is no supervision, or inspection by competent authority, in order to secure complete illustration of the points that have been made. In towns and villages of considerable pretensions closets are constructed in haphazard fashion, without any apparent appreciation of the points in reference to which care is most necessary. A closet should not be all open to the light of day, and buzzing, like a beehive, with swarms of flies. Its interior should be dark, and enclosed, so as to be fly-proof, and it should be properly disinfected at frequent intervals. It is improper construction of closets that starts many of the epidemics of typhoid in villages and the suburbs of cities that are commonly ascribed to bad water. It is true that on the introduction of a public system of water supply epidemics of this particular type cease, but this is due to substitution of plumbing for such miserable closet arrangements, rather than to any change in the water.

If contamination of wells does occur, it is secondary to that of the soil, and is much more uncommon than is generally supposed, there being, as we have seen, other ways in which the infection finds access to the body than through the agency of water. Hence, even in the case of a dairy farm, it is wise to consider the question of soil contamination in all its bearings, upon the origination and perpetuation of the disease, although this is one of the instances in which the mode of infection is very liable to be through bad water, employed in washing milkcans, and the like.

The infection of a public system of water supply, on the other hand, is, as a rule, through direct intermixture of fecal matter, usually in the form of sewage, rather than through soil contamination. It may be well to contrast this form of epidemic, particularly with that brought about by the agency of flies. When flies are responsible, there are little neighborhood epidemics, extending in short leaps from house to house without reference to water supply, or anything else in common. But when water is at fault the disease follows its use as a beverage wherever it may go, the only limitations being the resisting power of the individuals using it, and such household measures of boiling and the like as tend to destroy disease germs. Epidemics spread by flies tend to follow the direction of prevailing warm winds as though the fly wandering outdoors after contact with some source of infection had drifted with the wind; but nothing of the sort is perceptible in the case of water-borne typhoid. In villages and camps where shallow, open closets are in use, giving access of flies to the chief source of infection, flies are the chief medium of its conveyance. In cities where underground sewers carry such material beyond the ordinary reach of flies, whose migrations are not extensive, such diseases can become very prevalent only through infection of the source of public water supply. Hence in villages and camps typhoid is usually fly-borne and in cites water-borne. When a source of public water supply has been infected in this manner, cases of the disease occur throughout the year. When the conveyance is by flies the prevalence of the disease will be confined to a particular season exclusively. Thus in cities typhoid prevails at all seasons; in villages it is an autumnal disease. When the weather is dry and sultry flies have their best opportunity to convey the infection, or, in other words, under the very conditions best adapted to prevent its spread if water-borne.

It should, perhaps, be noted also that there may be a spore stage in the development of typhoid bacilli in which they may diffuse after the manner of gaseous emanations, being air-borne in this sense, the same as variola and rubeola, which are spread by particles large enough to affect the sense of smell, but too small to be seen by the aid of the microscope, being, perhaps, of veritable atomic minuteness. If this is the fact at any stage of development of the germ of typhoid, sewer gas emanations especially would then be dangerous, and require to be guarded against. It is a point worthy of further investigation.

But no matter in what manner conveyed, the spread of typhoid fever is absolutely preventible. Instant disinfection of typhoid stools, without a moment's delay on their passage from the bowels, solves the whole problem. This being done, there is nothing left for soil, air, water, or flies to carry. No physician or nurse in a large city should permit typhoid material to enter a sewer without disinfection. There are people down stream to be thought of. But when thousands of cases originate from river pollution, as in the case of the Mohawk and the Hudson some years ago, it is evident that very little if any care is taken. Nor do people in neighboring towns alone suffer the consequences of such neglect. In the very household itself there may be conveyance by flies through neglect of instant disinfection, and such infection of sewage pollutes soil, air, and ice taken from the stream, as well as water, so that the consequences may be far-reaching in many ways in the immediate neighborhood, as well as down stream. As against all this, such instant disinfection is an absolute remedy.

As regards the disinfectant to be chosen, not much needs to be said. For this particular use the sulphate of copper is well adapted, although there are many other disinfectants that may be employed. The difficulty with carbolic acid is that it is volatile, leaving nothing behind on evaporation to prevent reinfection. The sulphate of copper, on the other hand, remains behind on evaporation of its solution, so that its effect is very powerful and lasting, the soil thus impregnated with it also becoming a good disinfectant. For army use it is specially well adapted. The important point in regard to the whole matter is that with adequate disinfection in every case typhoid would become well nigh extinct in a single year. The walking cases would give the most trouble, but even they might be cleaned up if the thing were undertaken in earnest. It is surprising how rapidly even a lively epidemic at the most unfavorable season of the year has been checked by a none too nice application of the methods that have been suggested.

The subject is of exceedingly far-reaching importance. The sanitarian, and not the soldier, or statesman, is most likely to solve the problem of the extension of civilization and colonial expansion. Great armies and crusading hosts entering warm climates melt away, leaving not a trace. There are entire races of mankind who have learned to avoid the effects of soil contamination only by becoming nomads. And so there are vast areas of the earth's surface that are practically desolate, and great cities that have been in ruins for ages, in spite of attempts to reoccupy them again and again. A few points in sanitation would change all this, accomplishing more than all the generals and all the wars.

A Method of Fixing Bacteria without Drying.—Georg von Wendt's method is intended to facilitate the study of the finer details of bacterial structure without the possible damage incident to the usual method of desiccation. A platinum loopful of the culture is added to a drop of water in a watch crystal and stirred. A cover glass or slide is coated with a thin film of Meier's albumin glycerin and a few drops of water are allowed to fall on this portion of the glass. A loop of the diluted culture is then carefully touched to the surface of the water on the slide, when the bacteria will be seen to sink to the bottom in a fine well-defined cloud and the whole is covered with a large well-fitting watch crystal. At the expiration of twenty minutes to half an hour the bacteria will have settled and another drop or two of water is added. The watch crystal is replaced and the slide heated for eight or ten minutes in an incubator raised to a temperature of 75° C. In this way the albumin is coagulated and the bacteria are fixed to the glass without injury. As the preparation cools it is important to guard against the evaporation of the water, after which the usual staining and dehydrating processes may be carried out.—*Centralblatt für Bakteriologie, etc.*

ELECTRICAL REACTIONS OF THE GASTROINTESTINAL MUSCULATURE AND THEIR THERAPEUTIC VALUE.*

By G. W. McCASKEY, M.D.,
FORT WAYNE, IND.

Every question relating to gastric motility is vested with supreme importance to the practical clinician. If the motor energy of the stomach fails, secretion, however perfect in quantity and chemical composition, is practically useless. This is strikingly illustrated in some of Pawlow's experiments, in which, with motor paralysis and perfect secretion, the food next to the stomach wall was found in a state of active digestion, saturated with normal gastric juice, while a short distance away it was free from acid and in a state of rapidly advancing putrefaction. On the other hand, clinical observations furnish frequent proofs that symptomless digestion and adequate nutrition are entirely possible with a gastric secretion very defective in quality, if only motor power of the stomach is ample for the performance of its purely mechanical functions.

This is also largely true of the relative importance of the intestinal secretions and motor power, assuming, of course, the integrity of pancreatic and hepatic secretions. It is, therefore, an obvious proposition that in many, if not most, forms of chronic gastrointestinal disease the paramount problem is the restoration of motor power. The prognosis largely depends upon the possibility of this achievement.

Our means for accomplishing this *sine qua non* are varied in character and effectiveness. Proper nutrition and vascular tonus are, of course, fundamental requirements. Everything that will improve the nutrition of the body in general will, it should constantly be borne in mind, improve the nutrition of the muscular apparatus under consideration, in particular; while, on the other hand, those dietetic fads which are radically defective, either in proper balance or in total amount, must lower the nutritional state of the digestive tube in particular, as they do that of the body in general, and improvement thus obtained is illusive and transient. But assuming a rational view and practice concerning these basal propositions, the clinical problem before us is often difficult, and sometimes impossible of solution. In such cases, and perhaps in a considerably larger group, there are several auxilliaries which we can call to our aid, and it is to one of these, viz., electricity, that I ask your attention.

The obvious and frequently brilliant therapeutic results obtained in neurological cases would lead us, on purely *a priori* grounds, to expect substantial benefits from electrical treatment of muscular weakness of stomach and intestines. Such, indeed, are the claims made by many, though disputed by some, as a result of clinical observations, while experimental research has likewise given conflicting results.

In attemping to review the questions no pretense will be made to completeness of historical résumé, but I will, for the most part, limit myself to a consideration of my own clinical and experimental investigations.

Before dealing with the effect of electrical currents and impulses upon the muscular structure of the digestive tube, which lies sandwiched between mucous and serous membranes, it is necessary to consider the facility, or according to some, even the feasibility, of reaching the structures concerned The obstacle which has been assumed to exist is an extraordinary resistance to the passage of electrical currents on the part of the mucous membrane. I may say at once that I am fully convinced that the electrical resistance of the gastric mucosa is so slightly different, if different at all, from other tissues, as to be an entirely unimportant factor in the problem.

---

* Read before the American Gastroenterological Association, May 1, 1902.

This conclusion has been forced upon me by ordinary clinical observations, the phenomena of which appeared to me entirely irreconcilable with any unusually great electrical resistance of the stomach wall. For instance, with Einhorn's, or some other electrode within the stomach, which had previously been filled with water, or better, normal saline solution, and the circuit completed through another electrode applied to the skin, a given electromotive force would produce substantially the same or greater results than when the current was passed through an equal segment of the human body enclosed by skin on both sides instead of skin upon one, and gastric mucosa on the other. These results were determined in the case of the faradic current by the cutaneous sensibility, and, perhaps, the contraction of the skeletal muscles included in the circuit; and by the milliamperemeter in the case of the galvanic current with a given number of cells in which the electromotive force would be practically constant for a brief period of time. I would have, say five milliampers passing through the circuit. If now, the cutaneous electrode remaining stationary, the circuit leading into the stomach is broken, and replaced by another leading to the skin, the current passing through the meter will be inversely proportioned to the resistance. If the resistance is less, the current will be increased; if it is greater, the current will be diminished. This is simply a corollary of Ohm's law, and is incontrovertible.

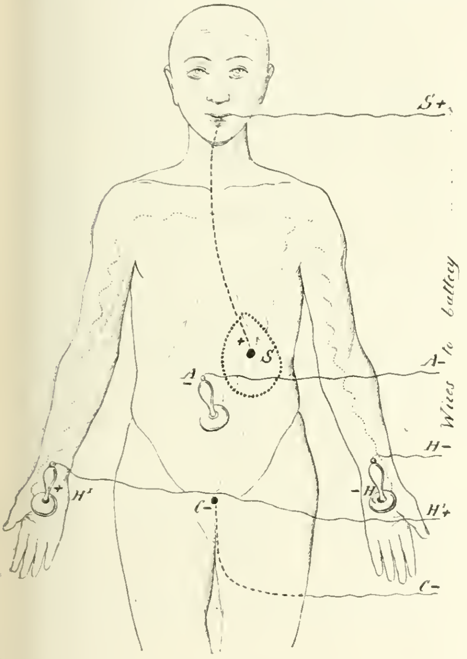

DIAGRAM 1.

Straight dotted lines, in this and subsequent diagrams, indicate the course of electric wires concealed withbin or behind body. "Wavy" dotted lines indicate the "paths" of electric currents.

S—stomach; A—electrode, over skin over stomach; C—interior of colon; S^1, A^1, C^1—wires connecting battery with corresponding electrodes.

The following experiment is one of many:

A piece of dental cable, tipped with a small nickel-plated metal bulb, was passed into the stomach (see diagram 1) of a patient suffering from a mild chronic gastritis, 300 cubic centimeters of normal saline solution having previously been poured into the stomach. An electrode with a surface of fifteen square centimeters, covered with absorbent cotton saturated with normal saline solution, was placed in the palm of one hand, and four volts of electricity passed through the circuit, S to H. This gave a current of 2 m.a., showing a resistance of 2000 ohms; the same electromotive force from stomach to skin (S to A) over epigastrium produced a current of 3 m.a., showing in this circuit a resistance of 1350 ohms; from one hand to the other one, and one-half m.a., or a resistance of over 2600 ohms; a rectal electrode was now introduced, and the circuit completed from thence directly to the stomach with precisely the same voltage (S to C), resulting in a current of 18 m.a., showing a resistance in this circuit of only about 220 ohms.

These figures have only an approximate and relative value. They were rather high because of excessive dryness of skin incidental to a bad nutritional state in those circuits which include the skin. They all include, further, the undetermined resistance of the metallic circuits; while the size and physical conditions of the electrodes, and especially the state of the skin, are variable factors, which rob such measurements of any absolute value. Their relative value, however (and that is quite sufficient for our present purpose), is unimpeachable, and, as a result of numerous experiments, I am able to positively assert that the resistance of the gastric mucosa is vastly less than that of the skin, after the latter has been placed in the most favorable condition. A circuit of the human body included between the cutaneous surfaces will invariably show more ohms of resistance than such a circuit, one end of which is skin and the other end gastric mucous membrane.

It would seem that the last experiment ought to be final, but in thinking over the possible fallacies, I thought that it might be objected that the low resistance of digestive tract was due to the fact that the current flowed the length of the digestive tube through the moisture, and fluid secretions contained therein.

In order to settle this matter, it occurred to me that I might use the skeletal muscles as a physiological indicator or meter for determining the penetration of the faradic current to the structures between the skin and digestive tract under two conditions: First, from stomach to skin; and second, from stomach to colon, the current, of course, remaining constant during both experiments. If the mucous lining of the digestive tube offered the very large resistance to the electric current which has been claimed by some to be the case, then it is perfectly obvious that a current passing from the gastric to the intestinal mucosa would have difficulty in penetrating the intestinal wall and stimulating the voluntary muscular apparatus outside of it.

The experiment was conducted as follows: One electrode, consisting of a plain insulated wire with the end exposed, was passed through the œsophagus of a healthy chloroformed rabbit into the stomach, and another similar electrode into the sigmoid, neither cavity being cleansed; a third large plate electrode of about 50 square c.m., covered with cotton saturated with normal saline solution was placed over the back in the lower dorsal region, the hair having been previously closely shaven. Upon passing a moderately strong faradic current from stomach to colon the entire voluntary muscular apparatus of the animal was thrown into a state of violent tonic contractions, proving conclusively that the current had not only penetrated the wall of the digestive tube, but had freely permeated the spinal cord, as it is only by this means that such extensive phenomena could be evoked.

The conductors were then so changed, without the slightest modification of the battery, as to complete the circuit from stomach to back. Although the path of the circuit lay directly through the spinal cord, the skin well soaked with salt solution, and the electromotive force absolutely the same, only the slightest muscular tremor of trunk and lower extremities resulted. By greatly increasing the current, extensive contractions ensued. These phenomena can only be explained by the undoubted fact of a very low resistance in the wall of the digestive tube.

Dr. Hemmeter relates an experiment in which the faradic current freely penetrated the gastric wall, and admits that under certain conditions this may occur. According to my observations it occurs constantly in health and disease, if there is either plenty of normal saline solution in the stomach in which the electrode is immersed, or a non-insulated electrode in contact with the gastric mucosa.

I have made a number of experiments with the gastric mucosa of rabbits, comparing the electrical resistance with that found in other mucous membranes, especially that of the tongue. In one experiment I passed the same current through six superimposed layers of gastric and lingual mucosa respectively. The conditions were made as nearly identical as possible with absolutely the same electromotive force, and with currents varying from .5 to 5 m. a. the current passing through the layers of gastric mucosa was slightly greater than that passing through the layers of lingual mucosa, thus demonstrating slightly greater resistance in the lingual than in the gastric mucosa, but the difference was altogether too slight to be of any practical moment. Furthermore, in my opinion, it was not really due to any intrinsic difference in electrical resistance, but depended rather upon variations in the contact between the layers, and especially upon the fact that the gastric mucosa was obviously moister than the lingual.

I have several times repeated the experiment made by Dr. S. J. Meltzer of faradizing the tongue of a rabbit, first, directly, and then by the interposition of a segment of gastric mucosa. I can fully corroborate his statement that the faradic response of the lingual muscle is greatly diminished, or even entirely inhibited, according to current strength and other conditions. But the inference that it proves an especially great resistance of the gastric mucosa relatively to other animal structures is, in my opinion, erroneous. If the experimenter had taken a piece of mucosa from another tongue and interposed it instead of the gastric mucosa, he would have found the same difference, either less or more, according to moisture, contact, etc. One of his own experiments with the omentum of the rabbit gives analogous results, but does not appear to lead to similar conclusions.

That there may be slight difference between the electrical resistances of gastric and other mucous membrane, I am not at all prepared either to affirm or deny; but if they exist at all, it is in degrees which could only interest the electro-physicist or electro-physiologist, but cannot possibly concern the practical therapeutist.

The resistance or rather the conductivity of the tissues of the human body, and indeed of any animal body, is for the most part dependent upon the fluids which the tissue contains. Dry tissue of any kind, whether it is mucous membrane, nerve structure, or muscular tissue, is a non-conductor. Water itself, is, indeed, a very poor conductor, but when, as is always true in animal structures, it contains salt in solution, it becomes a relatively good conductor. The electrical resistance of a tissue will depend, therefore, not to any great extent upon its histological structure, *per se*, but upon the amount of fluid which it contains in blood vessels and lymph spaces, and upon the proportion of salts which that fluid contains. The resistance of the same tissue must, therefore, obviously vary from time to time, as will also that of the entire body. For instance, Spehl and Sano (*Journal of Nervous and Mental Diseases*, 1897, p. 369) found the resistance of the body to drop from 1,450 ohms to 1,120 ohms after the ingestion of 4. of sodium chloride, which by its diffusion made the body fluids better conductors. The gastro-therapist has not to deal with any dry mucosa, or if he has, he proceeds to flood it with water before he attempts to penetrate it with an electric current.

But the electric resistance of the gastrointestinal mucosa is only one of the questions to be solved. Dr. Hemmeter correctly, but almost superfluously, remarks that it is not every current which is proven to penetrate the gastric wall that causes a contraction of its muscular layers. Owing to the conflicting results of previous investigators, I have gone over a great deal of the experimental ground myself in order to form an independent judgment. If typical peristaltic contraction could be demonstrated as a result of electrical stimulation of the digestive tube, it would furnish a rational explanation of the undoubtedly good results obtained by electrical treatment, and place the procedure beyond the shafts of therapeutic scepticisms.

Of the several possible methods of electrically stimulating the stomach and intestines, some are only applicable experimentally, and only of value as throwing light upon their physiology. Such, for instance, is the direct application of the electrode to the peritoneal surface, and direct excitation of the peripheral end of the divided vagus.

My own experiments upon animals have been made exclusively with rabbits, and very largely with faradism, as this is the form of electricity from which previous experience and analogy would lead us to expect the most tangible results. The faradic current which I used was furnished by a primary coil containing 100 feet of No. 18 magnet wire, and the secondary of 450 feet of No. 26 magnet wire, and usually about fifty alternations per second. Very slow alternations did not appreciably change results.

My experiments in faradizing the peritoneal surface of the digestive tube gave a constant localized contraction at point of application. This has been pretty uniformly found by other observers, and may be considered as fully established. In the stomach I have never seen the slightest semblance of a general peristaltic wave follow the localized contraction; but in the intestines this happens irregularly. The fact that muscular contraction can be produced so much more readily by stimulating the serous than mucous coat probably finds its explanation at least in part in the circumstance that the nerve filaments supplying the muscular fibers pass through the former, but do not pass through the latter. They are, therefore, more directly stimulated by the peritoneal application.

Faradization of the divided vagus has given no constant results in my hands. Indeed the investigations of Mr. J. N. Langley upon the visceral inhiting fibers of this nerve, if corroborated, would seem to preclude effective motor stimulation of the stomach through this channel. His experiments, which I have not undertaken to repeat, appear to demonstrate that for the cardia, and possibly the entire stomach, the inhibitory fibers in the vagus over balance the motor, or perhaps are more responsive to the forms of stimulation used.

Turning now to more purely clinical aspects of the question, we may proceed according to any of the following methods:

We may pass a current (1) from one area of mucous membrane to another in the same viscus; (2) through the body from skin to skin including any desired viscus between the points of contact; (3) from the mucous lining of the stomach or intestines to the skin; (4) from the mucous membrane of the stomach to that of the intestines, or *vice versa*.

The first method is so obviously unsuited to the stimulation of the muscular tunic that it can be at once dismissed. The gastric mucosa is, relatively to other structures, an excellent conductor of electricity, and the current would be, for the most part, expended there. In accordance with perfectly established laws, the mucous lining would receive all of the current for an undetermined distance from each electrode, beyond which the expanding path of the current would include the muscular wall, but with greatly diminished intensity.

The second, or percutaneous method, is much the simplest, and the least objectionable, so far as its technique is concerned. Its value must hinge very largely upon whether or not the current actually passes through these structures. It has been assumed by some that the therapeutic results were indirectly produced, and that the current passed around the body from one electrode to the other through the intervening structures without penetrating the stomach or intestines at all.

I am able to say that an electric current passed from the skin on one side of the body to the skin on the opposite side, does penetrate the stomach; and to prove it by an absolute demonstration, as is clearly shown in the following:

Experiment.—The stomach of a healthy anæsthetized rabbit was exposed, and completely divided by a transverse section (see Diagram II). In each half was inserted a heavily insulated copper wire with half an inch of the end exposed. The stomach wall was then ligated around each wire. The circuit of the galvanic battery was then completed from the skin covering the spine in the lower dorsal region with a large plate electrode, to the skin over the breast cephalad of the abdominal incision. Ten m. a. were then passed through the circuit. With the battery cells unchanged, and therefore with precisely the same voltage, the ammeter was taken out of the primary circuit and placed in the circuit with the two wires already described as connecting the two halves of the stomach. It registered three m. a. It is prefectly obvious that the only possible route by which the current could reach the ammeter was by traversing the skin and intervening structures and passing through the stomach. It will be observed that the stomach did not lie in the direct line between the electrodes, being prevented from doing so over an intact cutaneous surface, which was a requisite condition, by the abdominal incision. The stomach current would otherwise have been larger. I have no hesitation, therefore, in saying that in the face of this demonstration the penetration of the stomach by electric currents percutaneously applied is no longer a debatable proposition.

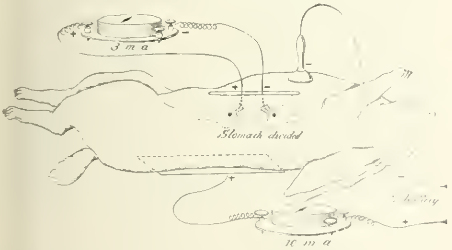

Diagram II.

The question of peristalsis of stomach and intestinal wall need not be considered. Even localized areas of visible contraction, such as are obtained by direct stimultaion of serous or mucous surfaces certainly do not occur by this method.

The third method—mucosa to skin—is correct in principal and practical in character. My experiments, which I have repeated many times, have given results slightly different from those obtained by Meltzer and others. So far as an efficient peristaltic wave of the stomach is concerned, I may as well dispose of that once for all by saying that I have found it absolutely impossible to produce it, or even a semblance of it, by any method which is clinically applicable. I have applied all current strengths, both galvanic and faradic, which come within the therapeutic range, with slow interuptions down to two per second, and so far agree with the investigators referred to in saying that it is quite impossible to produce a peristaltic wave of the stomach by any clinically feasible method of electrical stimulation.

But I must disagree entirely with Meltzer with reference to the production of a localized contraction of the stomach wall by the faradic current from mucosa to skin. If the intragastric electrode is a very small metal tip, and is pressed against the clean moist mucosa, a condition easily fulfilled, clinically, with a large plate electrode (50 to 100 sq. cm.) over the skin, I have regularly obtained a distinct localized persistent wave of contraction in the stomach wall. It was usually about one inch in length by one-fourth of an inch in breadth. This result was obtained with only slight, or sometimes with no contraction of the skeletal muscles.

I am unable to explain the discrepancy, but would call especial attention to two points which may possibly account for it. One is the very large size of the skin electrode, which diffuses, and therefore diminishes the intensity of the current over a relatively very large area of skeletal muscle tissue; the other is the very small size of the intragastric electrode, which limits the current to a very small area with corresponding intensification. It is an absolute law that the relative intensity of an electric current at any two points, or planes of its path, is inversely proportioned to the area of its transverse diffusion. The relative areas of the skin and intragastric electrodes, in my experiments, were more than 200 to 1. This would explain the slight stimulation of subcutaneous, and the intense stimulation of submucous structures. Unless Dr. Meltzer's electrodes were constructed along these lines, our results are not directly comparable.

If the stomach contains fluid through which the current passes no visible contraction can be produced.

If it were practical to move a small metal electrode over the mucous lining of the stomach, or better still a branched electrode, making several pointed applications to successive parts, the nutrition of the stomach wall could be modified and improved, much the same as an involuntary muscle is by such an application. For the present, at least, this is not practical, and would, necessarily, be somewhat haphazard in its application.

In the meantime we may seek for an explanation of the therapeutic results obtained by this method along other lines than those of either peristalsis or an active localized contraction. Putting aside for the present those influences which electricity is believed, and perhaps with good reason, to have directly upon nutritional processes, I have been able to satisfy myself by experimental methods of a phenomenon to which little or no attention has heretofore been given. I refer to a direct, immediate, and palpable increase in the tonus of the stomach wall—a true muscular phenomenon, but neither a peristalsis nor an active contraction limited to a small area. This occurs as a result of intragastric faradization and produces a change in the mass of the stomach which is perceptible to the palpating finger. The increase in intragastric pressure is very slight, amounting to less than one centimeter of a water manometer, but it can usually be demonstrated by the manometer and felt by the finger.

The tonus of a striated muscle is dependent upon a rapid and incessant series of impulses received from higher nerve centers, severance from which, as in a section of the sciatic, produces complete atony of dependent muscles, a condition which is closely simulated in the atonic states of the muscular wall of stomach and intestines in many chronic morbid states. I believe that a series of induction shocks which constitutes the so-called faradic current acting in a somewhat similar manner produce an increase of tonus, which may be more or less persistent, and which may, when sufficiently often repeated, as is necessary with many another effective therapeutic procedure, produce permanent results.

The fourth method, from stomach to colon, while inconvenient, is undoubtedly the most effective. It is perfectly obvious that a current passing through practically all the structures from the upper to the lower plane of the abdominal cavity has a better opportunity to exert its therapeutic influence upon the digestive organs, together with their nervous and vascular mechanism, than by any other method whatever. Practically, all experimenters agree in attributing greater electrical excitability to the muscular tunic of the intestines than to that of the stomach. By the method of application now being considered, I have been able with considerable regularity to incite a true peristalsis of both the large and small intestines after five to twenty seconds of continuous faradization. These movements were unmistakable in character, and efficient in extent. While they cannot be demonstrated clinically, there is every reason to believe that they occur, and I have repeatedly seen clinical results quite in keeping with this assumption in cases of intestinal atony.

These experiments were modified by opening the abdomen under normal saline solutions at body temperature. The intestines remained perfectly quiescent until the faradic current had passed several seconds, when very extensive and long continued movements ensued. They were even stronger and more widely diffused than when the intestines were similarly faradized after exposure to the air.

The experiment demonstrating the penetration of the stomach by the percutaneous method, and the other producing general tetanoid conditions by faradization from stomach to sigmoid, point unmistakably to the free conduction of electrical currents somewhat indifferently through the abdominal contents considered as a mass, the boundary lines of organs not forming insulating barriers to any great extent, if at all. This I believe is strictly in accordance with the established laws of electrophysics. It is the fluids of the tissues that form the conducting media, as all animal tissues without them would offer insurmountable barriers to the passage of currents of any ordinary tension. Now the abdominal viscera are in actual contact by their serous surfaces, which are freely lubricated by a normal saline solution. The fact that it contains viscid constituents is irrelevent to the question of electrical conduction.

In order to more clearly demonstrate the ubiquitous diffusion through the abdominal cavity of electrical currents passing from stomach to intestines, the following experiment was performed. Twenty m. a. were passed through the circuit. The skin of the trunk was then perforated at two different points between the planes of the two electrodes and copper wires (see Diagram III), placed in circuit with an ammeter inserted through the skin into the trunk. As soon as they passed the skin, a slight current was shown by the ammeter to be passing through the circuit, which increased as the wires penetrated more deeply, until, when they had penetrated one inch, three m. a. were shown.

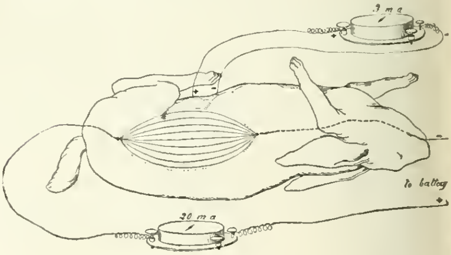

Diagram III.

This demonstrates that the current is widely, and very probably evenly, diffused through the abdominal cavity, somewhat irrespective of the limitations of the contained viscera.

The clinical technique of electrical treatment from stomach to intestines is not difficult. An electrode is passed into the stomach, which should contain fluid, and the patient then lies down upon the operating table and a second electrode is passed into the colon. If the faradic current is used, it is not necessary to have fluid in the bowel; with the galvanic this is advisable, and, with heavy currents, necessary. A current that can be easily tolerated is then passed from one electrode to the other for about ten or fifteen minutes.

As already indicated, the limits of this paper preclude any analysis of the work done by others. Two communications have appeared during the last year, both in the Ann. d'Electrobiology of Paris. The first, by Laguerrier and Delhern, attribute to galvanism effects which are so diametrically opposed to all established principles of electro-physiology as to challenge complete incredulity. They claim, for instance, stronger contractions at the positive than negative pole, which is entirely contrary to the well-known phenomena of electrotonus; also continuous contractions during the passage of the current, which is certainly unheard of in the electro-physiology of striated muscles and their nerves. Possibly we cannot compare the phenomena in the two neuro muscular systems, but it is difficult to believe that they could be so completely opposed.

However, so far as the therapeutics of the muscular tunic of the digestive tube is concerned, and the present inquiry has been limited to this phase of the question, faradism is apparently all that need be considered. It is quite possible that analagous results could be obtained by interruptions of the galvanic current, but that is less convenient, and it remains to be shown that it is even equally efficient.

That faradism can be used as a powerful auxiliary in the treatment of atony of the gastrointestinal muscles is a fact which I believe has been fully established by both clinical and experimental methods. Thus empiricism and science again salute each other, after many similar experiences, the latter illuminating the path which the former has blazoned through the wilderness of unguided human experiences.

I wish to express my indebtedness to Mr. Arthur Hadley, electrician, and my clinical assistant, Dr. B. W. Rhamy, for valuable aid in the experimental work.

Conclusions.—1. Electricity is a very valuable auxiliary in the treatment of muscular atony of the stomach and intestines, although adequate and properly balanced nutrition is an absolutely essential requisite.

2. Faradism is the preferable form of electric treatment, the effect of galvanism being problematical and not so well adapted to the purposes of muscular stimulation.

3. The resistance of the mucous lining of the disgestive tube offers no extraordinaryobstacle to the passage of either current.

4. Electric currents, when applied either percutaneously or with one or both electrodes in mucous lined cavities, pass directly through the abdominal cavity and the walls or parenchyma of the contained viscera, thus following the lines of least resistance.

5. It is impossible to produce a physiological peristaltic wave of the stomach by any method of electrical stimulation either experimentally or clinically.

6. Intragastric faradization, and possibly the percutaneous application, produce an obvious increase of tonicity of stomach wall, with palpable change of stomach, and slight, but measurable, shrinkage in volume.

7. Intracolonic faradization, and especially if the opposite pole is in the stomach, if continued several seconds, produces active intestinal peristalsis.

8. Localized contraction of both the intestinal and gastric musculature can be produced by local application of a concentrated current upon the mucosa; if continued, it will incite peristalsis in the intestines, but not in the stomach.

Loomis Sanitarium.—Dr. Herbert M. King of Grand Rapids, Mich., has been appointed Physician in Charge of the Loomis Sanitarium at Liberty. Dr. King is very favorably known to the profession for his researches in pulmonary tuberculosis, and brings to his appointment the skill and experience of an expert.

PENETRATING INJURIES OF THE EYE WITH OR WITHOUT THE PRESENCE OF A FOREIGN BODY IN THE ORGAN, AND THEIR TREATMENT.*

By J. MORRISON RAY, M.D.,
LOUISVILLE, KY.
CLINICAL PROFESSOR OF OPHTHALMOLOGY IN THE UNIVERSITY OF LOUISVILLE, ETC.

A more fitting subject could not have been selected for consideration this evening than that with which your most worthy president has honored me. Injuries to the anterior segment of the eyeball and foreign bodies within the eye are most often seen by the general practitioner at the time of their inception. Upon his judgment often rests the responsibility of the future usefulness, not only of the injured organ, but also of its fellow. Made up as this society is of general practitioners as well as specialists in all departments of our works, questions which admit of discussion by all must prove of mutual benefit.

The subject has been so often and so well presented to the profession that I can hardly expect to offer anything new, but its great importance justifies the hope that its free ventilation will lead to more prompt action in the treatment of extensive wounds involving the so-called dangerous region of the eye, especially when such wounds are accompanied by the retention of foreign particles.

Injuries of the eye offer for solution questions different from those presented by injuries of other organs. Whether to sacrifice or attempt to save the damaged organ is of serious moment, and a decision vexes the most experienced.

The general surgeon has no more important question to test his surgical acumen and knowledge: even where life itself is involved. To many it appears an easy question to decide. When an injured eye is blind, remove it they say, and thereby stop all possibility of future trouble to the fellow eye and responsibility in the case ends. But the conservative surgeon, on the other hand, will assume the responsibility, and often, by judicious care, a useful organ is obtained that works with the fellow in performing its functions.

The present seems to be an opportune time for the summing up of our knowledge of eye injuries and their treatment. The more thorough application of the principles of antisepsis in dealing with such injuries, and the more widespread use of the electro-magnet in removing magnetizable particles from the eye, have induced a conservatism in dealing with wounds and foreign bodies, the wisdom of which can only be proven by a close clinical study of cases.

No department of surgical work has been more thoroughly impressed by the adoption of the principles of antisepsis and nowhere have their beneficent effects been more apparent than in the treatment of eye injuries.

A well known English authority in a recent discussion remarked that, "since the antiseptic treatment of wounds of the eyeball, combined with the removal of all tags of tissue, suturing all wounds, and covering them with conjunctiva, had become more general, the necessity for excising the eye was not so great."

Schirmer, the author of the classic study of "Sympathetic Ophthalmia," in the new edition of Graefe and Saemisch, has recently asserted that the internal administration of mercury to the point of tolerance is the surest safeguard against future trouble in dealing with infected perforating wounds of the globe. In an experience extending over six years and including sixty-two cases of infected wounds of the eye, he met with no case of sympathetic trouble developing and in only 31 per cent. of the cases was enucleation eventually required.

---

* Read by invitation before the Medical Society of the County of New York, April 28, 1902.

Wounds of the eyeball are of serious import, according as they are located in or near the ciliary body, and the danger is greater or less in proportion to the amount of injury sustained by the structures of or in close relationship with this part of the organ.

In dealing with eye injuries the questions demanding prompt consideration can be classed as follows:

1. In penetrating injuries of the eyeball how shall we manage the wound, and what shall be done with the structures so often found protruding?

2. If the presence of a foreign body is suspected, what is its character, and what steps are necessary for its removal?

3. What are the dangers of sympathetic involvement, and what are the best means of prophylaxis?

4. If the injuries to the tissues and integrity of the organ are beyond repair, shall enucleation be performed at once or later?

If the injury is a large penetrating one, the structures found protruding will depend upon what part of the eye is the seat of the wound.

If it is corneal and extends backward to the plane of the iris, the structures found in the gap are always iris and possibly portions of the lens and its capsule.

If the line of incision is in the region just external to the sclero-corneal margin, the protruding tissues may be iris, cilliary body, lens or vitreous.

If the penetration is far back vitreous, choroid and retina may protrude from the gaping scleral wound.

If the wound contains only the iris within its grasp and is seen within a few hours of its reception, a replacement may be attempted, provided that the parts have first been thoroughly cleansed. This should be brought about by careful scrubbing of the regions in proximity to the eye. The edges of the lids, cilia and caruncle, especially cleaned by friction with an alkaline solution. The conjunctiva should be flooded with a bi-chloride solution of 1–5000, especial care being given to the cul-de-sac, but under no circumstances should the chemicals be allowed to enter the eye.

With a delicate spatula the iris is gently disengaged from the angles of the wound and pushed into its proper place. If the anterior chamber contains much blood or foreign material carried into it by the penetrating object this can be removed by allowing a gentle stream of warmed normal salt solution to flush the anterior chamber.

If the patient is an adult local anæsthesia by a sterile 4 per cent. solution of cocain or 1 per cent. holocain may be produced. In children a general anæsthetic should always be employed.

If the iris is lacerated and hangs in shreds from the lips of the wound it should be excised, the very greatest care being necessary to disengage the columns from the angles and from the lips of the wound.

If the wound is of many hours duration lymph so binds the iris that perfect separation is impossible. The lips of the wound should be coapted and a binocular bandage applied. In twenty-four hours, when the anterior chamber has begun to reform, a solution of atropine, 1 per cent. should be instilled into the eye. No drug in my experience has had any influence in dilating or contracting the iris so long as the aqueous has not been partially reformed and no dependence can be placed either on mydriatics or myotics in disengaging the iris from the wound.

Many of the penetrating wounds involving the cornea and extending into the ciliary region are made by blunt objects and therefore the wound is often found to be irregular and extending in different directions. In such cases it is frequently impossible to properly approximate the lips of the wound, and thereby the danger of infection and violent secondary reaction is increased.

If an effort is to be made to save such eyes something must be done to bring the lips of the wound together, in order to protect it, during the healing process, from the invasion of infectious organisms. Here a pressure bandage to produce immobility of both eyes is of great value, for as the aqueous humor reforms the corneal flaps may fall into proper position and the wound unite kindly. If, however, this does not appear possible a suture may be employed. The method adapted by Kalt after cataract operation may be tried: a very sharp curved needle with a fine silk suture is passed into but not through the cornea on each side of the wound and then the lips are brought into apposition.

When the wound involves the sclera overlying the ciliary body the necessity for excising the protruding tissue is far greater than when the iris is involved, for so long as tissue is left in the line of separation no complete closure will be affected.

After incision the wound can, in my experience, be most easily closed by a silk suture passed well into the episcleral tissue and conjunctiva. Sutures that penetrate the sclera are a source of irritation, and catgut has not proved reliable.

My personal experience leads me to the opinion that we do not attach the proper amount of importance to the grave possibilities of an incarcerated iris, especially when found at the sclero-corneal margin with a protrusion forming a cystoid cicatrix. To me it presents a constant menace to the eye. Within the past few years I have seen four eyes presenting this character of injury go to destruction from a purulent infection starting at the point of incarceration. Two of these were eyes that had been successfully operated upon for cataract and were useful seeing eyes. One was a case in which, as a result of the ravages of a gonorrheal infection one eye had been lost and the other perforated by a marginal ulcer that had healed with a large mass of iris incorporated in the cicatrix with but little protrusion.

In the fourth the iris and possibly the ends of the ciliary process were incorporated in the wound. In each case as a result of a slight trauma the thin layer of epithelium covering the iris was destroyed and infectious organisms gained entrance, producing a destructive purulent irido-cyclitis.

Recently Berry has advocated treatment in such cases, maintaining that a cystoid cicatrix should never be left as the risk of infection is very great. He claims the best method in dealing with cystoid swellings is the use of the galvano-cautery.

De Gama Pinto has recommended that the cicatrix be exsected thoroughly and that a piece of conjunctiva, obtained by transplantation from a distant point, be implanted.

A more rational method appears to be that advocated by Pagenstecher and more recently recommended by Snellen and De Wecker. It consists in covering the incision with conjunctiva. If the wound is near the sclero-corneal margin and not too extensive a narrow band of conjunctiva is dissected up external to the seat of the line of separation transplanted over the wound and stitched into this position. Or, as De Wecker claims, the entire conjunctiva around the sclero-corneal margin may be loosened up and brought over the cornea in purse string fashion. As soon as the conjunctiva becomes adherent to the line of former separation the stitches are removed and the remainder of the membrane retracts to its normal position. The part adhering to the wound effectually closes it and protects any iris or ciliary body that may be caught in the wound, from future danger of infection.

I have recently observed the value of this method. A colored man, in attempting to drive a nail, hit it a glancing blow so that the nail flew from the hammer and struck him on the lower inner corneal segment with much force. When I saw him a few hours later there was found a large rectangular wound starting near the pupillary margin of the cornea and extending about 3 m.m. to the opaque limbus, then 2.5 m.m. along the limbus upward. The iris protruded from the wound, while the edge of the lens and the vitreous protected by the zonule were in contact with the incision. The anterior chamber contained a quantity of blood, and only light projection and perception were good. The surroundings were carefully cleansed and the conjunctival sac thoroughly irrigated with a boric acid solution. The protruding iris was excised and with a spatula the lips of the wound were cleared. It was found impossible to coapt the triangular piece of cornea that formed the flap so that it would stay in position, and there was danger of the lens being forced into the wound. To protect the line of injury, I dissected up a strip of the conjunctiva corresponding with the scleral edge of the wound, loosening it thoroughly, then made a slit in the conjunctiva at the limbus above and stitched the conjunctiva across, covering more than half of the cornea and the wound. I am convinced that this saved the eye from complete destruction, as the gaping wound would have become infected and the eye lost. The eye showed but little reaction and in a few days the conjunctiva was firmly adherent to the line of the corneal wound and the anterior chamber reformed. When last seen he could count fingers. The pupil was drawn toward the wound, and the cornea, for about 2 m.m. of its inner lower segment, was covered with conjunctiva very suggestive of a pterygium.

Gifford has recently recommended a similar method in protecting the remnants of the cornea in atrophied eyes when the wearing of an artificial eye has become painful.

It is a common observation that when the injury is confined to the ciliary zone extending from 2-6 m.m. back from the sclero-corneal line and the solution of the tissue not great, it constitutes the most dangerous of any to which the eye is subjected. Such wounds are most often made by small sharp, penetrating objects such as a thorn, the blade of a knife or scissors, or the tine of a fork. The penetration is usually deep, the wound is small and closes quickly, thus preventing the outflow of blood and intraocular fluids that would tend to wash out the septic material carried in by the instrument with which the wound is made. Under such conditions the vitreous contains large quantities of blood and furnishes an ideal culture medium for the propagation of the septic germs that were carried into the eye.

Randolph suggests that in large wounds, where the lens is injured, it should be removed, since the swelling that takes place in the lens material produces pressure on the ciliary body, fills the wound with escaping lens substance, prevents approximation and thus favors inflammatory reaction.

The best local application to limit reaction is cold: iced cloths will be found valuable in controlling inflammation and allaying pain. When, however, infection has occurred and panophthalmitis is pending, heat is pleasant, hastens liquefaction and shortens the active inflammatory stage.

If the presence of a foreign body is suspected in the eye, what is its character and what steps are necessary for its removal?

In penetrating wounds where the presence of a foreign body is suspected, the question of diagnosis is of the very greatest importance, and an early decision of the matter of the greatest moment. A history of the manner in which the injury was received with the local appearance of the organ, and the presence of tenderness or a pricking sensation on pressure, immediately after the inception of the injury, will be found of value in making this decision.

The injury resulting from particles flying from two pieces of metal coming forcibly in contact with each other and the eye containing a quantity of blood are strong evidences of the presence of a foreign body. If the injury is from shot and the wound is jagged and lacerated, the indications are that the shot is either in the eye or has traversed the organ and found lodgement in the orbit.

The personal history, as furnished by the patient, is always of some value, but it will often mislead. Positive evidence is now fortunately at our command by the use of the *x*-ray. The localizing method of Sweet in this country, or that of Mackenzie Davidson to be seen at Moorfield's, not only furnishes evidence of the presence of a foreign body in the eye, but its exact location in the organ.

The different substances which pass through the ocular tunics and find lodgement in the eye are of a variety of material, such as stone, glass, copper, shot and iron. Fortunately, the larger number of such cases occur in manufacturing centers where iron or steel is the offending particle. In my experience the most dangerous has been stone. Every eye that has come under my observation containing particles of stone has been lost, either by the severity of the original wound or by infection later from noxious particles carried in by the foreign body.

Leber has drawn attention to the chemical changes excited by the presence of a piece of copper as, for instance, particles of percussion cap lodged in the eye, and the very great danger of their exciting destructive changes in the organ, distinct from the mere influence of the traumatism.

In considering the method of dealing with these cases and the prognosis, we must take into consideration what part of the organ has been injured and in what portion of the eye the foreign body has found lodgement. It may be, (1) in the anterior chamber or iris; (2) in the crystalline lens; (3) loose in the vitreous; (4) lodged in the ocular tunics in the posterior segment of the organ.

The most hopeful of eye injuries with a foreign body present are those in which the particle has penetrated the cornea and remained in the aqueous chamber or found a point of fixture in the iris. Such foreign bodies can often be easily removed by a corneal section and properly constructed forceps. The precaution, however, must be taken to have the patient in the horizontal position, lest when the aqueous humor escapes the particle should become dislodged and drop down behind the opaque limbus where it would be lost to observation and difficult to remove.

When the foreign body has penetrated the deeper structures the danger will depend most upon the nature of the material of which it is composed.

Only in cases when the object is of a magnetizable nature can any assurance of a preservation of the organ be offered. Before the use of the large magnet a scleral incision was necessary and recovery from the result of the trauma was exceptional.

The practical application of the large electromagnet for the removal of particles of iron or steel from the interior of the eye marks a triumph in modern ophthalmology. As Barkan remarks, "Nothing can be more brilliant than to watch the exit of the offending particles from the tissues of the eye and, following the force of the wonderful power, fly to the instrument."

My experience with the use of the magnet is limited. Within the last two years I have seen six cases of steel in the eye where the magnet was used for its removal. In one of these cases the penetration was corneal and the particle of metal was lodged in the iris. After corneal section the particle quickly flew to the instrument. The operation was done within a few hours after the injury and a perfect eye resulted.

In another case the injury was of a similar nature yet the foreign body penetrated partly into the lens. It was easily removed by a corneal section. Traumatic cataract developed; after the absorption of the lens 20-30 vision with proper correction was obtained.

The third case seen in consultation, was one where a serrated sliver of steel entered through the ciliary region and buried itself in the lens. The magnetic force could be seen to make the lens come forward, but the object was so firmly impacted that it could not be gotten from its bed. The lens became opaque and later was removed along with the foreign body.

Three cases were seen where the particle penetrated the vitreous. In one the foreign body entered through the sclero-corneal limbus making a wound about 3 m.m. long. The case was not seen until the following day when a spongy exudate in the pupil and lymph in the anterior chamber indicated an infection already well advanced. When the eye was brought to the magnet, pain denoted the presence of a foreign body. In a few seconds the bulging of the iris indicated that the foreign body had passed through the suspensory ligament, into the posterior chamber and, coming from behind the iris through the pupil, it was easily removed by enlarging the wound of entrance. The infection present at the time of removal ran a mild course, and while the eye is useless as far as seeing is concerned, it has for eighteen months remained free of irritation and with good tension.

In another case a meridional incision was necessary to remove the foreign body which had entered through the ciliary region and found lodgement deep in the vitreous, which at the time of removal showed evidences of purulent infection, and later enucleation of the eye was found necessary.

In still another, seen some days after the reception of the injury, both the *x*-ray and the electro-magnet proved of no value and when the eye was enucleated a long, slender particle of steel was found firmly imbedded in the sclera near the posterior pole.

I believe in magnet operations that the sooner it is resorted to after the reception of the injury the greater will be the chances of getting out the foreign body and the less the chance of infection. After the metal has been allowed to remain for forty-eight hours or longer it becomes firmly imbedded in the lymph which has been deposited and the force exerted by the magnet on small particles is so slight that the foreign body cannot be extricated from its surroundings. Further, the oxidation going on exerts a chemical irritating effect that lessens the resisting power of the tissues and tends to increase the danger of infection.

The advantage of a quick extraction far outweighs in importance the knowledge of the exact location of the foreign body. The use of the *x*-ray is always a source of delay. However, when the offending particle is other than a magnetizable metal, the *x*-ray localization is of great value as an aid to any form of instrumental removal.

The statement made by Knapp years ago, namely, "that the cases of successful or partially successful removal of foreign bodies from the vitreous chamber and its surrounding walls are so rare that they may be considered almost as an exception," is now refuted by Knapp's own report of his results in such cases.

In any consideration of injuries of the anterior segment of the eye with or without the presence in the organ of foreign material the question of sympathetic ophthalmia necessarily presents itself. Since Mackenzie called attention to the fact that in individuals who had lost one eye as the result of an injury the other eye is not infrequently attacked by inflammation and becomes blind, the question of sympathetic diseases of the eye has been one of ever increasing interest. In no other part of the body have we an analagous condition.

It is scarcely in order for me to take up a discussion of the question as to whether the occurrence of sympathetic ophthalmia is due to impressions transmitted along nerve channels or to infecting particles carried by the blood, or lymph spaces. Much has been written and much is yet to be found out. Clinically we are familiar with its results, yet the picture is not always a typical one. The most frequently observed form is a plastic inflammation of the uveal tract, characterized by ciliary injection, punctate deposits on Decemet's membrane, fine dust-like opacities in the vitreous and, if seen early enough, usually changes of an inflammatory nature in the optic nerve head. Later, posterior adhesions to the lens capsule and fibrinous exudates extending over the lens and ciliary body occur. These lead sooner or later to loss of vision. This clinical picture results from almost identical changes going on simultaneously in the injured eye. The shortest time after the receipt of injury in which this process has been noted has been fourteen days, yet it may be delayed for as many years. Children seem to be slightly more liable to its ravages, and eyes that have been the subject of former inflammation are peculiarly prone to its development. In fifteen years experience I have seen it develop under observation only once. The eye sympathetically affected was the seat of corneal opacities from an old phlyctenular disease and was defective in seeing as a result therefrom. This defect led the family and surgeon to postpone preventive enucleation with the hope that the injured eye might eventually become the better.

In addition to the well-defined symptoms of inflammation as just noted, frequently a purely functional neurotic condition known as sympathetic irritation shows itself, characterized by clouding of vision, disturbance of the light sense, lachrymation and numerous subjective sensations. This condition lasts often for a long time without producing functional changes. Again it may be the forerunner of a violent and destructive inflammation.

Sympathetic eye diseases do not occur as often as might be inferred by a casual glance at the literature on the subject. Fuchs quotes Cohn as estimating that 10 per cent. of the blindness throughout the world results from injuries of the eye. Of these, one half, or 5 per cent., of all blindness is due to sympathetic diseases. The percentage given by Magnus and the report of the Ophthalmological Society of the United Kingdom is only slightly less than that estimated by Cohn, 4.5 per cent. Among two hundred children in the Kentucky State Blind Institute I found 3 per cent. blind as the result of sympathetic ophthalmia following injuries. Ohlman found in five hundred and fifty-six severe injuries that sympathetic ophthalmia occurred only twice.

A great many loose diagnoses of sympathetic irritation and even sympathetic inflammation have been made. We must bear in mind that when the eye has been the seat of inflammatory action whether traumatic or idiopathic the fellow eye cannot perform its accustomed duties. The irritation we often see in one eye, the fellow being the seat of a relapsing irido-cyclitis, due to a discrasia, should not be classed as sympathetic but as a result of the diathetic condition.

In making a proper decision as to whether an eye should be enucleated or not a number of important questions offer themselves for solution. First and foremost is the danger of sympathetic ophthalmia. Seldom is the primary injury sufficient to destroy the ability to perceive light and as sympathetic ophthalmia does not develop until sometime later an opportunity should be given for repair in the wound, guarding carefully against the danger of infection by strict aseptic detail. If proper surgical knowledge is used in clearing the wound and it heals kindly without septic infection, the danger of the fellow eye becoming involved is not great, and the eye may eventually become of value. If the eye contains a foreign body that cannot be removed, if the wound fails to heal kindly, or if after healing the scar becomes depressed and the globe tender on pressure and with diminished tension, it should be removed without delay. The presence of an infectious inflammation involving all the ocular and orbital tissues constituting a panophthalmitis, is cause for delay unless the violence of the inflammatory action should appear to influence the general condition.

Harmless blind eyes are better than glass ones, and usually they offer a good foundation for the prosthesis. At the present time patients demand some consideration from a cosmetic standpoint, especially in early life. The lack of symmetry in the development of the two sides of the face when one eye has been removed in childhood is a fact of importance, nevertheless the contrary is held by many. Gordon Byers, in the measurement of ten adult orbits from which the eyeball had been removed in childhood found no difference between the two sides. Congenital anophthalmos shows a decided deficiency in orbital development. In my experience, when the eye has been removed in childhood and an artificial one has been constantly worn both the orbit and the facial muscles on the side of the absent eyeball show tardy development.

Ernest Thompson has recently proven that in animals this deficiency amounts to from 10 to 15 per cent. and involves all the bones entering into the formation of the orbital cavity.

In adults, especially mechanics, the loss of an eye or the removal of a defective eye detracts seriously from their ability to obtain employment and at the same time lessens their earning capacity. Magnus and Würdeman estimate that this loss amounts to from 27 to 30 per cent. for the first year after the accident and from 18 to 20 per cent. after this time.

Without a desire to minimize the danger to which certain eyes are exposed by the fact of the mate being damaged, I would urge a wise conservatism in dealing with injured eyes that have a chance for sight and are not the seat of an inflammation, for, if no infection occurs, they may eventually be of service.

QUANTITATIVE CHANGES IN THE BLOOD IN PULMONARY TUBERCULOSIS.

By MARTIN L. STEVENS, M.D.,
PHYSICIAN IN CHARGE OF THE WINYAH SANITARIUM, ASHEVILLE, N. C.

It will be impossible to treat exhaustively every phase of this subject within the limits necessarily placed upon a paper of this kind. In consequence some things that are really important will be omitted or receive only brief mention. For the same reason I will omit references to many of the contributions on this subject. Blood work has received much attention in the past few years, and blood conditions in tuberculosis have been looked into by a large number of careful investigators. By these investigators the facts in regard to some matters have been well established, and in regard to others strikingly different conclusions have been arrived at.

Perhaps in no other diseases are the clinical pictures presented by the patient himself, and by a drop of his blood so paradoxical as in the one under consideration. In but few diseases are the external signs of anæmia more clearly stamped upon the individual. The extreme pallor, the blue-white sclerotics and the transparent ears, lead us to expect blood conditions which the laboratory findings do not verify; while the blood itself, on examination, presents to us values that almost make us doubt the accuracy of our methods. This is illustrated by taking the figures representing the average values found in the examinations of one hundred cases of pulmonary tuberculosis, which I select from data of examinations personally made as representing all stages of the disease. These averages show:

For Males—red cells, 5,039,000; white cells, 14,060; hæmoglobin, 76.7; worth, .76; specific gravity, 1056.

For females—red cells, 4,373,000; white cells, 12,666; hæmoglobin, 72; worth, .73⅔; specific gravity, 1054⅔.

In view of the fact that these examinations were made at an elevation of some 2,300 feet above sea-level, and cannot on that account be compared with those made elsewhere, without taking into consideration the modifying effect of altitude, I insert here the average values found in examining at the same level the blood of a limited number of healthy persons. These averages show:

For males—5,912,000 red cells, and 101 per cent. hæmoglobin.

For females—4,745,000 red cells, and 91 per cent. hæmoglobin.

But one cannot speak in general terms of the blood in tuberculosis, because of the variation in the quantity of its various elements in the different stages of the disease, and even among different cases in the same stage.

Red Cells.—The number of erythrocytes in the first stage of the disease is usually quite suggestive of one or the other of the two distinct types that are generally characterized as first-stage cases. In one of these types is usually found infiltration of a part of one or both upper lobes, without open lesions, and extreme paleness, with or without emaciation. The number of red cells corresponds well with the external evidence of anæmia, as in the case of Miss W., aged eighteen years, blonde, of fairly good physique, but very pale; temperature, 97° to 99.4°; has infiltration of both apices; red cells 3,742,000 per cmm.

In the other type with a circumscribed region of infiltration, occurring in persons apparently in perfect health, with no loss of flesh and with no external evidence of anæmia, one finds usually a normal red blood count. These cases are seldom seen during the closed stage of the disease, as there is nothing to call their attention to the disease at this time. A case will illustrate:

Mr. T., aged thirty-nine years; weight, 162½ pounds; of excellent physique and color, has had no sickness in twenty years. Consulted a physician two weeks before on account of a slight cold, attended with cough. A tinge of blood in the expectoration led to a microscopical examination of the sputum, and the detection of Koch's bacilli. Temperature 98° to 99°. An examination of his blood showed 5,448,000 erythrocytes per cmm.

The former of these types includes the greater number of those cases which run a rapid course with fatal termination. It is probable that in at least some of them the anæmia antedates the tuberculosis, thereby lessening the resisting power of the system against infection and against the progress of the disease after infection has taken place.

In the chronic cases that have little or no fever, and that have no active destructive lesions, one meets the most striking blood conditions. These cases, almost without exception, show extreme pallor and more or less emaciation, and yet their blood count differs but little or not at all from the normal. The average for this class has been 5,329,000 for males, and 4,458,000 for females, while the highest count was 6,288,000, and the lowest 3,680,000.

In those cases with destructive processes in progress, accompanied by an intermittent or remittent fever, such as is usually designated hectic or septic and which we are accustomed to ascribe to a secondary infection with pyogenic organisms, as distinguished from the slight variation in temperature, found in the class last mentioned, there is frequently seen a temporary increase in the number of red cells, amounting in exceptional cases to 7,000,000, this increase being followed, if the fever is long continued, by a lessening of their number, which lessening progresses with the continuance of the septic fever.

In the more advanced cases of the same class, with further evidence of sepsis, profuse sweats, profuse discharge from open surfaces in lungs, both of which, together with the temperature, would be expected to concentrate the blood and give us higher values of the various elements, the blood condition is even poorer than in the same class that do not lose the liquids from the body in this way. The erythrocytes are diminished in number, sometimes as much as a third or a half. However, of the extreme cases of this kind I have but little data, as I have refrained from exposing very sick persons to the little pain incident to getting the specimen without an apparently beneficent motive.

In acute pulmonary tuberculosis, accompanied by high fever and rapid disintegration of the lung, there is a marked decline in the number of cells.

Among the complications that modify the number of the erythrocytes hemorrhage, of course, must be given first place, the number of cells diminishing in proportion to the quantity of blood lost. The rapidity with which blood regeneration takes place depends upon the physical condition of the patient, and upon the ability of the digestive organs to digest and assimilate food. Seldom is the previous count regained under a month after a hemorrhage of any size. After repeated small hemorrhages, cell regeneration may take place even more slowly.

In amyloid degeneration the erythrocytes run progressively low.

Diabetes is said to produce blood concentration in those cases complicated by it. Only two cases of this kind have come under my observation. These gave counts of 5,700,000, and 4,600,000 respectively, which do not differ essentially from those of cases without this complication. Conclusions, however, cannot be drawn from so small a number of cases.

Summarizing, we find a lowered red count in the acute cases, in a part of the anæmic incipient cases, and in a part of the septic cases, while in the chronic second-stage cases, representing a great majority of consumptives, we find, in spite of their pallor, in spite of their cavities, and in many cases in spite of their temperature, a normal number of red cells. This paradox is only explained when we consider the quantity of their blood. Every one who observes carefully, must be impressed with the unusual smallness of the superficial veins in the consumptive, whose capacity for carrying blood is thereby much lessened, and at the autopsies one notes that the diminution in the volume of blood corresponds with the shrunken appearance of the superficial vessels. So that, although we have as yet no means of accurately determining the quantity of blood in the living body, it is at once apparent that in tuberculosis we have, as Grawitz[1] says, a true oligæmia; that is, a lessening of the entire blood mass, though a given quantity of it may contain a normal number of erythrocytes.

One of the reasons given for the blood concentration in tuberculosis is the profuse sweating, the profuse bronchial secretion, and in some cases the diarrhœa. Theoretically, this looks all right, but it does not accord with clinical experience. Those cases in which the secretions are greatest—that is, in which there is the greatest evidence of sepsis—show less blood concentration than was found in the same cases before the secretions became so profuse, and the highest counts are obtained in those cases in which these so-called blood-concentrating causes do not exist. Therefore, if sweats, diarrhœa, etc., are a factor in bringing about blood concentration, this effect is overbalanced by the destruction of blood resulting from the attendant septicæmia. This blood destruction is, as various investigators have shown, in some cases quite rapid. I have seen the number of erythrocytes drop 700,000 in less than five weeks in the presence of conditions such as are supposed to cause concentration, namely, sweats, expectoration and diarrhœa.

The experiments of Gärtner and Römer[2], and of Grawitz[3], a decade ago, have also been made the basis of an explanation of the high blood count found in these cases. These observers found that injections of caseous tubercle, tuberculin and allied products cause a disturbance of balance between the fluids within the blood vessels and in the tissues of the body outside of them, resulting in an excessive flow from the former to the latter, with consequent blood concentration. But these experiments, suggestive as they are, cannot in themselves be accepted as conclusively explaining the blood conditions of phthisis. Tubercle bacilli products do not react in the same manner on the tuberculous and the non-tuberculous. Furthermore, the system rapidly becomes tolerant to their influence, reacting much less to large doses after a time than to small ones at first, so that until their effect is observed under circumstances such as obtain in cases of tuberculosis, where the products of tubercle bacilli metabolism are liberated in the system slowly and in gradually increasing amount, and where there is tuberculous tissue present to modify their physiological effect, this matter will have to remain *sub judice*.

Hæmoglobin.—The hæmoglobin value of the blood in all stages of the disease is low as compared with the number of red corpuscles. This is true even in those cases in which its amount, according to Fleischl, is 100 per cent. or more, as well as in those in which it does not reach half that figure. The worth of the corpuscle varying usually between 50 and 90, and averaging for males 76 per cent. and for females 73⅜ per cent. The complications, hemorrhage, sepsis, malassimilation of food, etc., influence it in much the same way, but in greater degree than they influence the number of erythrocytes.

It was Laache[4] who first called attention to the discrepancy between the blood count and the appearance of the patient, and who after the examination of a small number of cases, in which the red cells were nearly normal in number, decided that phthisis does not of itself tend to the production of anæmia. This opinion has been sanctioned by practically every later contributor to the subject, though all have recognized the presence of a certain number of anæmic cases. Cabot[5], the pioneer of blood work in America, to whom we owe so much, says, that "pure tubercular disease, whatever its seat, has little or no effect upon the blood," and ascribes blood changes, when present, to the concurrent sepsis. Lazarus[6] speaks of the disease as one which can progress until productive of considerable emaciation and still show normal hæmoglobin and corpuscle count. And in the authoritative works, which have come out in the last year, Ewing[7] notes the presence of anæmia in many cases, yet finds that "normal blood is found in many phthisical patients who do not sweat or suffer from diarrhœa, Dacosta[8] introduces his chapter on tuberculosis with the statement that "a pure infection with Koch's bacillus of tuberculosis is capable of producing comparatively slight alteration in the composition of the blood," and ascribes such changes as may be associated with tuberculous processes to secondary infection and not to the disease *per se*. He also states that[9] "in a large proportion of tuberculous patients, neither the hæmoglobin nor the erythrocytes fall below the normal standard, this being the rule both in incipient cases and in those which, although of greater chronicity, have escaped mixed infection, or have successfully withstood the ill effects of the constitutional drain." The examinations which I have made lead me to a somewhat different conclusion. If we understand anæmia to be a "deficiency in corpuscle substance; that is, in red cells, in hæmoglobin, or in both" then I have found anæmia present in all stages of the disease, and independent of complications, the anæmia being characterized by deficiency of hæmoglobin without necessary change in the number or size of the erythrocytes, and therein differing from chlorotic anæmia, to which it bears resemblance. This anæmia may be, and in some cases no doubt is, a preexistent condition, which continues after the development of the tuberculosis, but it can hardly be so in all the cases not complicated by a secondary infection. The exceptional cases in which the blood worth reaches 100 have not in my examinations occurred sufficiently often to invalidate the fact that anæmia is a characteristic of the blood in phthisis. The hæmoglobin has reached 95 in but 4 per cent. of the cases, and this at an altitude that should give us high blood values. On the other hand, it has been below 60 in but 8 per cent. of the cases. These figures, as well as some others presented herein, are not in full accord with those recently given by Appelbaum[10]. He reports the average hæmoglobin in the second stage of the disease to be as high as 90 to 95 per cent., and, like others, puts night sweats and diarrhœa in causal relation thereto, and to the normal count also found in this stage. The facts which I have already set forth concerning the relation of these causes to the number of erythrocytes apply in even greater measure to their relation to the amount of hæmoglobin.

Specific Gravity.—The specific gravity in many cases of phthisis is below that of normal blood. As compared with the amount of hæmoglobin present, however, it is in most cases a little higher than either the table of Hammerschlag or Schmaltz would indicate. This relatively high specific gravity is more marked in those cases in which the blood worth is low. This, however, we should expect. And this fact only illustrates the defect in the method of estimating the hæmoglobin from the specific gravity, without taking into consideration the number of red cells.

Leucocytes.—The number of leucocytes varies between quite wide limits, and a knowledge of the number in each and every case is a matter of great clinical importance, confirming or denying the conclusions arrived at by physical examination, and making clear the condition in many doubtful cases, and giving us data, which, if considered along with that to be obtained by other methods of examination, will aid materially in prognosis.

In the acute miliary form of the disease, which runs its course without suppurative process, in the first stage of chronic pulmonary tuberculosis before pyogenic infection has taken place, and in fibroid phthisis, there is found a normal number of leucocytes, or, if the number of erythrocytes is diminished the number of white cells may also be correspondingly reduced. In tubercular pneumonia there is always present a marked leucocytosis, which, however, is not usually so great as in the pneumonia due to the presence of the pneumococcus. Deaver[11] has called attention to the fact that after excluding pneumonia, leukæmia, etc., we can from a marked leucocytosis always safely infer the presence of pus or its consequences. This finds abundant verification in the blood examinations of phthisis. Moreover, the extent of the leucocytosis bears some relation to the acuteness and extent of the destructive process, being greatest during abscess formation, and lessening but not disappearing after rupture of the same, and during the sloughing process, or the granulation process which follows.

A notable exception to the rule above stated is found in a few of the septic cases, in which, with gradually increasing sepsis, we find a low or lessening leucocyte count. In tuberculosis, as in other diseases, complicated by pyogenic infection, this condition indicates feeble resisting power on the part of the system, and is of greatest prognostic import. The few cases of this kind which I have seen have promptly died. A high leucocyte count under the same conditions is a better omen.

After pulmonary hemorrhage there should be a leucocytosis of from 10,000 to 20,000, dependent partly upon the amount of blood lost, and partly upon the recuperative power of the system, a high count indicating greater reserve power than a low one under the same circumstances. This increase in the number of white cells does not begin as quickly as is the case after traumatic hemorrhage, but is frequently delayed as much as twelve hours, and continues from one to four or more days.

Dry cavities in arrested or cured cases do not in themselves occasion any increase in the number of white cells.

Marked elevation of temperature in phthisis is usually attended by an increase in the number of white cells, but this increase is dependent upon the lung condition (pneumonic or septic), and bears no direct relation to the temperature itself.

Summary.—The number of erythrocytes is usually higher than the appearance of the patient would suggest, amounting in many cases to a normal count.

A low count, when present, is suggestive of low resisting power, or an unfavorable complication.

The usual explanation as to the cause of blood concentration is not fully confirmed by facts.

There is a true oligæmia in the majority of the cases.

The hæmoglobin and the corpuscle worth are so uniformly subnormal as to justify the conclusion that anæmia is a characteristic of pulmonary tuberculosis.

The specific gravity is low, but a little higher than corresponds with the hæmoglobin.

The number of leucocytes varies from one-half to four or more times the normal number dependent upon the stage of the disease, the character of the infection, the resisting power of the individual, and the presence of complications.

In any given case their number may have both diagnostic and prognostic import.

A CLASSICAL EXAMPLE OF LANDRY'S PARALYSIS.

By WILLIAM BROADACRE PRITCHARD, M. D.,
NEW YORK.
AD. MENTAL AND NERVOUS DISEASES, N. Y. POLYCLINIC; CONSULTING NEUROLOGIST, S. K.

TYPICAL examples of Landry's paralysis are rare. The anomalous is the rule. Of six instances in which the diagnosis was tenable, which number constitutes the entire personal experience of the writer during fourteen years of special work, in one only were the symptom picture and collateral history classically exact. These facts are assumed to be of sufficient interest and importance to warrant a record of the following case: On Tuesday, August 27, 1901, I was asked by Drs. Townsend and Coonley of Staten Island to see W. M. L., male, aged twenty years, suffering from a paralysis of somewhat abrupt onset. The patient, a young man of excellent family and personal history, of good habits and vigorous, athletic physique, had been ill in bed for three days only, although for more than a week he had complained of excessive lassitude and general weakness. On the 17th, while out sailing in an open boat, dressed only in a bathing suit, he had gotten thoroughly wet in a sudden shower. He allowed his wet clothing to dry on his person and the temperature dropping considerably after the shower, he became quite chilled. The only ill effect, however, noticed for several days afterwards, was the general malaise mentioned. On Saturday, the 24th, he came home from business in a state of marked physical prostration following a severe chill. He complained of severe backache and registered a temperature of 101°–102°. Throughout Sunday his condition remained much the same, the temperature continuing with but little variation. The following morning the muscles of the left foot and ankle were found to be paralysed, a few hours later the other foot and both legs became affected and by night the paralysis had extended upwards, implicating successively the abdominal and thoracic muscles and finally the arms, shoulders and neck. The urine could not be voided, catheterization becoming necessary. After the onset of paralysis all subjective pain ceased. On Tuesday when the man was seen by me, the condition was as above described. the paralysis being complete and of the flaccid type. The only motion possible in any of the extremities was slight flexion of the fingers and of the second toe of the right foot. All reflexe—splantar, knee jerks, cremasteric and abdominal—were absolutely abolished. All forms of common sensibility appeared normal except a diminished pain sense when tested with a deep pin prick. Respiratory function was markedly affected and seemed to depend upon the abdominal and throat muscles, there being only faintly perceptible movement of the intercostals. Deglutition was well nigh impossible and the voice was much weakened. Each cranial nerve was, on careful examination, found to be quite normal, although the ciliospinal pupillary reflex was sluggish and the right pupil larger than the left. On exposure, the patient's entire body became covered with a mottled blush, indicating vaso-motor paresis. All mental functions and faculties were perfectly normal, the patient remaining acutely and pathetically conscious of his condition. An absolute insomnia had persisted for seventy-two hours. The pulse was weak, thready and rapid—110 to 130—but without intermission. Continuous hot saline irrigation with active mercurial inunctions were suggested and employed, but without the slightest perceptible effect, the patient dying from paralysis of the pneumogastric the following night. Autopsy was refused.

105 WEST 73D STREET.

The Shape of the Tuberculous Chest.—Woods Hutchinson holds that the tuberculous chest, instead of being flat, is round—that the anteroposterior diameter, instead of being diminished relatively to the transverse, is actually increased. In the normal chest the posterior surface of the chest wall is sufficiently flat to allow the inner surface of the scapulæ to rest comfortably upon it, and the shoulders fall back easily and remain naturally in the erect or military position. In the rounded chest of the child, or of the consumptive, the scapulæ, having no flat surface on which to rest roll forward in the direction of least resistance, and come to rest, almost on the anterior wall of the chest. So that flatness of the chest is merely an index of the position of the shoulders. Almost incredible as it may seem, he contends, the healthy vigorous human chest is of the broad, flat, well-expanded, low-indexed type. The author says that he is aware that his two hundred measurements are not sufficient to prove his theory, and hopes that other physicians will collaborate with him in ascertaining the facts in the case.—*The Medical Examiner and Practitioner.*

Bilious Remittent Estivoautumnal Fever.—Ira B. Bartle reports sixty-two cases treated the past year. In eighteen the attack was aborted, making the duration from three days to a week. To abort the fever he has used but two methods—one the use of Warburg's tincture, and the other ten-grain doses of quinine at 6, 8, 10 and 12 A.M. The former was used in twelve out of the eighteen cases, with calomel two grains every two hours until four doses were taken, then twenty to thirty grains of sodium phosphate three times a day, together with a tablespoon of Warburg's tincture at 7 and 10 A.M. Eight of the cases of fever showed decided typhoid symptoms. Quinine was here of little value, but merely increased the nervous symptoms. Out of the sixty-two cases mentioned, one died of hemorrhage, and the other probably from perforation.—*Oklahoma Medical-News Journal.*

THE PHYSICAL BASIS OF HEREDITY.

PROFESSOR Carl H. Eigenmann of Indiana University contributes, in a recent issue of the *Popular Science Monthly*, a well-considered article on the above theme. The transmission of mental traits has always been a subject of peculiar concern to scientists, as well as of serious disputation. Some contend that mental peculiarities are always handed down to an individual's descendants, to a greater or less extent, others hold that these gifts or faults of the mind are only sometimes transmitted, and yet another contingent perseveres in the belief that such occurrences are merely accidental.

Professor Eigenmann steers a middle course and states as his opinion that mental peculiarities are transmissible. Sometimes one mental trait of the parents is transmitted to one child, while others are transmitted to another. However, allowance is made for the effect of environment, especially of education, overcoming hereditary tendencies.

Galton has determined just how much, on an average, each ancestor contributes to the peculiarities of an individual. The parents together contribute one-half of the total heritage, the four grandparents together one-fourth, the eight great-grandparents one-eighth, the sixteen great-great-grandparents one-sixteenth, and all the remainder of the ancestry one-sixteenth.

Referring to this, Dr. Eigenmann says: "This law explains another—that the offspring of exceptional parents are, on an average, less exceptional than their parents Supposing that the average height of two parents exceeds the average height of the race by three inches. The average of the grand parents and remoter ancestors will differ from the average height of the race by much less than this. Since the ancestors beyond the parents contribute one-half the entire heritage of the individual, they will act as a drag to pull the individual toward mediocrity, in the present case by one inch. This law acts impartially, so that the offspring of the extremely good and the extremely bad are both saved from the fate of their parents. This regression toward mediocrity may readily be overcome by selective breeding. In race-horse breeding, if the ancestry has been good for three or four generations, the rest are not considered.

Mediocre parentage has little or no influence on the talents of offspring. "Among mankind we trust largely for our exceptional men to extreme variations occurring among the commonplace." Men of genius are necessarily isolated, in that they possess but few relations exceptionally gifted.

As to the physical basis of heredity, Dr. Eigenmann discusses the matter from a broad standpoint, and points out that each method of forming new individuals is restricted to some limited group of species. In the great majority of animals sexual reproduction is the only means of transmitting characters to a new generation. This, of course, is usually produced by the fusion of two cells.

With regard to the advantages of the production of a new individual by the union of two cells, the writer says: "That on the part of some it is looked upon as the union of two hereditary tendencies, which eliminates extreme badness, or what amounts to the same thing, extreme goodness that may be inherent in one of these tendencies, and at the same time insures new combinations of characters from which nature may select the fit. On the part of others it is looked upon as a means of rejuvenescence or union of energies to insure the continuance of life for another span.

Loeb has found that an egg that will under all normal conditions develop only after a male cell has entered it, may be caused to develop without the male cell by placing it for a short time in a solution of higher osmotic pressure than that in which it is normally found. It is thus seen that one function of the male cell is to supply stimulation to the egg to cause it to develop, to regain the lost power of dividing, to rejuvenate it or to act as a catalyzer. But it has long been known that the child may inherit from the father. Indeed, Boveri has shown that the male cell can also develop alone into a new individual, if it is supplied with a proper medium of sufficient size."

Boveri further shows not only that hereditary qualities are compressed into two cells, one just large enough to be seen with the unaided eye and the other far to small to be seen without the microscope, but he has demonstrated that the hereditary plasma is restricted even to certain parts only of these cells. From a series of experiments it was concluded that the nucleus of a cell contains the physical basis of heredity.

Again the character of any cell is controlled by the nucleus it contains, and, since it has been shown that the nucleus contains two different groups of chromosomes, one group containing the peculiarities of the father and the other the peculiarities of the mother, the cause of the blending—says Dr. Eigenmann—of the two sets of characters in the offspring becomes apparent and the greater resemblance in some characters to one parent and in other characters to the other parent may be readily inferred.

These explanations of how mental traits may be, and probably are, transmitted are worthy of close attention, although, perhaps, too much stress is laid upon hereditary transmission of mental peculiarities. Nevertheless, when it is considered that the possession of inherited traits is by Dr. Eigenmann taken for granted, and that the paper was written with the object of showing the manner in which this result is brought to pass, no objection can be made to the trend of the argument. There is no doubt that mental peculiarities are transmitted, but not to the extent believed by some. A tendency to do right or to do wrong is more often the outcome of environment, bringing up and education than of heredity.

A young child is naturally imitative to a degree, and is strongly influenced by those around him, and his character is mainly formed in youth.

At the same time it cannot be denied that mental traits may be transmitted, and there would seem to be no inherent reason why they should not be inherited on a physical basis.

THE PATIENT AND THE FEE QUESTION.

Not many months ago an eminent surgeon of this city charged a very large fee for the performance of an ordinary operation on a man of great wealth, and was forced to be satisfied with one-fifth of the amount named. The outcome of the settlement was not what was expected, and from many points of view the operator was placed in the embarrassing position of virtually acknowledging that not only was the gross sum an extravagant one, but all in excess of the demand took the aspect of a swindle. Such, at least, was the legitimate assumption of the client in view of the acquiescence of the professional gentleman to the bargain of the large reduction of the figures. There was no excuse for the latter on the score of the inability of the patient to pay any reasonable fee. Nor can it be claimed that the services rendered were not of incalculable value to the patient, whose life might otherwise have been forfeited.

The whole question narrowed itself down to the matter of alleged excessive charge, and the surgeon implicitly confessed to the truth of the indictment. It is just such transactions as these that lower the proper estimate which should be placed upon skilled professional services. There is just as much a mistake in placing the fee too high as too low. In other words, a maximum fee should be properly considered and then adhered to at all hazards. The charge should be right in the first place, and when the patient is able to pay there should be no compromise on the mere basis of actual value of the services to the recipient. All other modifying circumstances may be taken into account save those which refer to the abstract justice of the pecuniary part in the transaction. The mistake made by the surgeon in question was the virtual acknowledgement that one-fifth of the fee was, after all, a satisfactory amount.

As a vindication of principle, it would have been much better either to have trusted to the uncertain outcome of a jury trial than to have given the patient the right to decide the question in his own favor.

Whatever the legal verdict might have been under the circumstances, the surgeon could then have had the satisfaction, even under an adverse judgment, of maintaining that he was right notwithstanding. As it is, the patient quietly chuckles over an opportunity of placing his own value on the service, and of reporting his triumph to his wide and influential circle of acquaintances. It would appear better, rather than submit to such a condition, to run the risk of losing the fee altogether and saying in the end that the charge was right, no matter what the patient might believe.

Although a medical fee for special services is always sufficiently expansive, in view of special circumstances making it so, the patient has a right to believe that it is ultimately fixed on the arbitrary standard of a purely commercial transaction. The physician or surgeon must not be in doubt on this point any more than he is in giving his other doses to his patient. This is the only basis of mutual responsibility in discharging reasonable obligations. So long as there is a pecuniary element in the transaction, it is evident that such obligation should be measured by a monetary standard. The price should be fair and the sum should be fixed. This gives due dignity to the service and proper satisfaction on the *quid pro quo* standard. There is no reason for varying this rule, save in the exceptional instances when the patient is absolutely unable to meet the demands. Then the compromise is a concession to his poverty rather than a virtual admission that the bill is excessive.

While extraordinary services may command special prices, it is nevertheless just and right that the every-day visits should be fixed by an absolute charge previously understood by the patient. All these points are so self-evident that it seems hardly necessary to refer to them save in connection with the subject of the editorial text.

QUACKS IN AUSTRALIA.

Medical men in the United States frequently—and with justice—complain of the unfair competition to which they are exposed at the hands of Christian Scientists, Faith Healers, Osteopaths, and various other members of the quack fraternity.

But the lot of the medical practitioner in this country is blissful compared to that of his fellow practitioner in Australia.

In no part of the world is the unqualified, ignorant medical pretender given so great license as in the aforenamed British colony. There is no proper medical law there, nor is any restriction placed on the doings of the quack; on the contrary, the duly qualified medical man is unjustly discriminated against and every facility is afforded the illegitimate practitioner to gull the public and incidentally to fill his pockets.

The New York *Evening Post* of June 8 quotes from an article on the subject which recently appeared in the London *Daily Mail*, written by an individual who is apparently well acquainted with the facts of the case.

In part this writer says as follows: Statistics prove that each legitimately qualified practitioner living in Australia strives for his bread in competition with three quacks, but if the law does not protect the qualified man, and despises the health of the community thus impiously exposed to the ravages of impostors, the charlatan himself it takes to its heart and nourishes as though he were a precious jewel.

Thus, if a man suffer from the negligence or malpractice of a qualified surgeon or physician and can prove his case, the law gives heavy damages to the injured one. But if a like injury be suffered at the hands of a quack, the law non-suits the plaintiff, remarking, with a wag of its asinine head, "My dear sir, you have no case! If you employ a quack to attend you, you do so at your own risk. You have no legal redress!" Strange but true! What wonder then that Australia is the happy hunting-ground for quacks.

Again, restrained by the absurd chains of custom and rigid, iron-bound etiquette, a properly qualified medico dare not advertise. He may be a gold-medallist, an F.R.C.P., an F.R.C.S.; he may possess the talents of a Treves, a Gull, or a MacCormac; but if he so much as insert a card in a newspaper he is cut thenceforth and for all time by his professional brethren. He is, therefore, obliged to spend the best years of his life waiting idly behind his door-plate, often vainly, for the public, to discover his abilities. The quack, on the other hand, suffer no bushel to hide his light. No etiquette fetters his movements. He covers the advertising pages of all the afternoon city dailies and the country weeklies with the announcement of his fictitious qualifications, with perjurious statutory declarations concerning the marvellous cures he has effected, and with glowing accounts of his heaven-inspired genius."

This is a realistic word picture of the difficulties with which the medical man has to contend in Australia, withal it is convincing and conveys a true impression to the mind of the state of affairs medical in a country where there are no protective laws either for the physician or the public. New countries have the idea that they must cast off all old-world trammels and prejudices, that such are hurtful to freedom, and they always end by rushing into excess, to their own detriment.

It is obvious to every reasonable and sane person that laws which do not permit an incompetent individual to practise medicine—who holds, as it were, in his hands the balance between life and death—is to the advantage of everyone concerned—indeed, is of supreme importance to the community at large. When it is said that one man, a herbalist, and prince of Australian quacks, pays income tax on an annual revenue of $150,000, that he can just write his own name and read large print, and that there is no legally qualified surgeon or medical practitioner in Australia who earns more than $30,000—one may draw his own conclusions.

As to the remarks of the writer in the London *Mail* with regard to the foolishness of the etiquette which prevents a qualified medical man from advertising in the slightest degree the ethics of the profession rightly demand that this unwritten law be strictly observed.

It is sufficient protection to their own interests and to the welfare of the general public if the law will insist that no person who has not gone through a proper medical course, and passed the required examinations, shall be allowed to practise on equal terms with those who have done so.

MAGNESIUM DIOXIDE.

A discovery has been made recently which is claimed to be a remarkable achievement in chemistry and of considerable therapeutic value. Dr. Friedrich Elias, a Berlin scientist, has succeeded in evolving by a chemical process of his own devising, a magnesium dioxide (MgO_2) which he asserts is capable of emitting a large amount of diffusible oxygen throughout the system. This preparation, which is not a synthetic product, occurs as an impalpable white powder, tasteless, colorless, odorless, non-astringent, non-irritant, non-toxic and insoluble in water. Dr. Henry Leffman, Professor of Chemistry in the Woman's Medical College, Philadelphia, and Vice-President of the British Society of Public Analyses, has analyzed magnesium dioxide and makes the statement with regard to its composition that it contains no barium, strontium or calcium compounds. It is free from sodium dioxide and caustic potash, therefore possesses no caustic properties. It is also declared to be capable of exuding large quantities of diffusible assimilable oxygen. It is claimed that this preparation exerts beneficial effects in the treatment of diseases arising from deficient oxidation. If magnesium dioxide be as easily absorbed by the capillaries as is stated to be the case by those who have tested it clinically, it should prove a therapeutic remedy of much value.

ARSENIC AND FOOD.

In the *London Polyclinic* there have appeared of late articles on the relation of arsenic to food and incidentally as a cause of cancer. It would appear to be an undoubted fact that arsenic is contained in many more articles of food than is generally supposed. All beer made from malt dried over coke is liable to contain arsenic, and when, as in Manchester and district some months ago, the amount of the drug which is present in the beer is excessive the results are disastrous to health and life. Again long continued taking of the mineral in small quantities will give rise to a number of nervous affections.

On the other hand, as an editorial in the *Polyclinic* (June) points out, there is a bright side to the shield. Arsenic in medicinal doses possesses most remarkable powers in the control of many very serious diseases, and in the much smaller doses in which beer-drinkers usually receive it, it is simply a very efficient tonic, and that thus, although some may have suffered from arsenical beer, a large majority have been benefited. Nevertheless, while it may be freely conceded that arsenic in infinitesimal doses, such as beer should contain, is beneficial to health, yet the statement is just as indisputable that the continued ingestion of arsenic in moderate or even medicinal doses is usually followed by unpleasant if not dangerous symptoms. The amount of arsenic contained in any article of diet should be, therefore, rigidly restricted well within the limits of safety.

THE CHANCES OF LONG LIFE.

In the MEDICAL RECORD, some time ago, the subject of longevity was touched upon, and several instances were cited in which individuals were shown to have reached a span of life far beyond the ordinary limit. Most of these examples, however, occurred many years ago, and their authenticity is not wholly beyond doubt.

M. Jean Finot is quoted in the *Literary Digest* (May 31) as bringing forward instances of longevity which quite put to the blush any cases mentioned in the RECORD. He refers to a resident of Genoa who is said to have reached his four hundredth year in the enjoyment of all his intellectual faculties; a Scotchman who lived to be over 200 years old, and various monks of Mont Athos who have reached 150 years. He asserts that Servian statistics for 1897 show three persons between 135 and 140 years old, 18 from 126 to 135, 123 from 115 to 125, and 290 from 105 to 115. In 1890, there were, he says, in the United States 3,981 persons over 100 years of age old and 21 in London.

The most satisfactory feature with regard to M. Finot's views is that he does not believe that the average length of human life has been reduced. On the contrary, he believes that it is constantly increasing, owing to the progress of hygiene.

In answer to the question why do we die at all the writer answers, "For three reasons: First, want of physical exercise in the open air; second, poisoning by microbes which the phagocytes have not succeeded in destroying; third, fear of death." Nevertheless, comforting though M. Finot's optimistic ideas as to longevity in the present time may be, there are other philosophers who by no means agree with his conclusions. M. Henri de Barigny on the contrary thinks that some two thousand years ago a man of 68 or thereabouts was likely to live longer than a modern Englishman of the same age. His reasons for thinking thus are as follows:

"Evidently there was among the Egyptians a natural selection, resulting from environment that does not take place to-day, at least to the same degree, among civilized people. The Egyptians who reached the age of 68 years had robust constitutions, and therefore their chances of longevity were exceptional. Mortality was higher among the children and the adults, and there was a kind of selection by death. The man of to-day is not stronger; he is possibly weaker. But the majority of the people live under conditions more favorable to longevity, because we know what conditions to promote. In other words, the greater expectation of average life is the result of the progress of sanitary science in the fullest sense, and not the result of increase of vitality. It is the consequence of the evolution of man's intellect rather than of the evolution of his body." It is for these reasons that M. de Varigny asserts that although the chances of life have increased for infancy, youth, and the prime of life, they have not increased for old age.

M. de Varigny, in fact, is merely one of the numerous band of exponents of the survival of the fittest theory. Human life in general is prolonged to an extent not dreamt of in the days of the ancient Egyptians, when weakly children would probably have been promptly killed, and when only the constitutionally strong had a chance to survive. It is still a debatable point as to which custom is the best for the race at large.

DIET.

There has been recently issued a flood of literature bearing upon "what we should eat and what we should drink," some of which is illuminating and instructive, while some is sublime nonsense.

Sir Henry Thompson, who has been for long an accepted authority on the diet question, has just issued a small book which he informs us, in the preface, is the same as that first published in 1866, when he was sixty-five years of age, with the addition now that he has reached eighty-two, of about an equal amount of material verifying his earlier experience and observations, and an appendix on sugar. Sir Henry Thompson is continually being brought forward by rabid vegetarians as one of the foremost exponents and advocates of a wholly vegetable diet. On the contrary, he declares that while "sympathizing to a large extent myself with the practice of what is called 'vegetarianism' in diet, and knowing how valuable the exclusive, or almost exclusive use of the products of the vegetable kingdom may be for a considerable number of the adult population of our own and of other countries, in the temperate zones, and for most of that which inhabits the torrid zone, I object strongly to a dogmatic assertion that such limitation of their food is desirable for any class or body of persons whatever."

Another useful book on dietetics has been written by Dr. W. Gilman Thompson. This is a work of ambitious scope and contains a mass of information on all points bearing upon diet. Dr. Joseph E. Winter of New York has written a monograph on the food factor as a cause of health and disease during childhood, a pamphlet which will be of much value especially during the hot season. But of all the literature which has been contributed on the matter of eating, that being published in the *Lancet* at present is perhaps on the whole, the best.

Dr. Harry Campbell, physician to the Northwest London Hospital, is writing for the *Lancet* a series of articles, which he terms "Observations on Diet." Referring to the manner of food most suitable to man the writer says: "But while man is carnivorous he is also herbivorous, *i. e.* he is by nature omnivorous, a mixed feeder. Some races subsist wholly on animal, others solely on vegetable, food, but taking the whole world over it is found that man thrives best on a mixed diet. *i. e.* experience, which is, in the last resort, the only reliable test, confirms the conclusion derived from ancestral and anatomical considerations, and the accumulated experience of many countries through many ages goes to show that man thrives best on a dietary in which proteids, fats, and saccharides bear a certain proportion to one another. Now this proportion cannot be obtained on a purely animal diet or on a purely vegetable one. In the former case a quantity of proteid greatly in excess of his requirements has to be consumed in order to secure the necessary quantity of carbon, and in the latter the needful quantity of nitrogen can only be obtained by consuming an excess of saccharides and cumbering the alimentary tract with a large mass of food, which is objectionable not only for mere mechanical reasons but on account of the enormous demands it makes upon the digestive system, to which it diverts a large amount of blood and energy which might be employed elsewhere. These difficulties are got rid of by combining animal and vegetable food so as to secure a proper proportion of the various nutritive ingredients, that proportion being obtained by taking about one of the former to two of the latter. If the diet be too much animal or too much vegetable certain evils result."

Treatment of Chronic Suppuration in the Frontal Sinus.—H Lambert Lack sums up the treatment for this condition as follows: (1) In all cases of suspected suppuration in the frontal sinus intranasal treatment should be tried in the first instance. This consists in securing free access to the lower end of the infundibulum by removing the anterior end of the middle turbinate, part of the uncinate process, and opening up the anterior ethmoidal cells, at the same time removing any polypi or other obstruction that may be present, followed by simple nasal irrigations for a few weeks. In favorable circumstances this may be followed by cautious attempts to wash out the sinus through its natural opening, but on no account should an attempt be made to forcibly enter it from the nose; (2) If this method fails and serious symptoms are present, the frontal sinus should be opened externally, and should be obliterated when it is not very large; when the posterior wall is carious or perforated; when cerebral symptoms are present; and even when the sinus is large if the patient does not object to the risk of deformity; (3) In all other cases a free opening should be made into the nose, and free drainage maintained until all suppuration has ceased. Operations providing external drainage only are insufficient, and operations allowing of intranasal drainage for a limited time only are both inefficient and dangerous. —*Edinburgh Medical Journal.*

News of the Week.

The Next Surgeon-General of the Army.—It is announced that the President has designated Col. R. M. O'Reilly to be surgeon-general of the army to succeed General Forwood, who will retire on September 7 next. Colonel O'Reilly will have until January, 1909, to serve as surgeon-general. He was appointed from Pennsylvania as a medical cadet in 1864. He is a graduate of the medical department of the University of Pennsylvania.

Sanitary Matters in Cuba.—The Cuban Government has appointed Dr. Charles Finlay as Chief Health Officer for the island of Cuba. This is an excellent appointment, and one that augurs well for the continuation of the high sanitary standards which have been established in the island. The Chief Quarantine Officer is Dr. Eduardo F. Nuñez, a graduate of the University of Pennsylvania. He practised for several years in Philadelphia, was acting assistant surgeon in the U. S. Army during the Spanish War, and since that time has been engaged in sanitary work in Havana and other cities of the island. The U. S. Marine-Hospital Service has transferred to the Cuban Government five completely equipped quarantine stations, and fourteen minor stations. At a dinner given in Havana in honor of Dr. Gorgas and the unexampled success of his sanitary labors in that city, Dr. J. Santos Fernández paid a graceful tribute to him and his work. In expressing his pleasure that Dr. Gorgas was to remain in Havana in order to ensure a permanency of the results already obtained, he added that his words were more significant because he had never been a partisan of the revolution, and had not believed the Americans would act in the way they did. But now he acknowledged his mistake and was glad to do so, and he hoped he might always be mistaken in the same way if it would be to the advantage of his country.

Money for Isolation Hospitals.—The Board of Estimate and Apportionment in this city has appropriated for the year 1902 the sum of $37,000 "for the purpose of defraying expenses required for the preservation of the public health, and the care and maintenance of patients suffering from contagious diseases." It is understood that the particular object which the health authorities had in view in asking for this appropriation was the renovation of some of the structures which are now used as smallpox hospitals on North Brother Island.

The Purity of Bottled Table Waters.—The Board of Health has adopted an amendment to the sanitary code, looking to a standard of purity for artificial and bottled table waters. Every manufacturer and importer or other persons who manufacture or import mineral spring or other drinking water will be required to file under oath with the Health Department the name of such water, the exact location from which the water is obtained, together with a chemical and bacteriological analysis thereof, also stating when the water was manufactured, the exact formula used in its production, giving qualitatively and quantitatively each and every item entering into its composition. Any one failing to comply with these requirements will be refused a permit.

Medical Scorchers in Buffalo.—Three physicians in Buffalo were recently arrested for speeding their automobiles, their excuse being that they were out on hurry calls. An appeal was thereupon made to the Superintendent of Police to allow physicians to exceed the legal speed when necessary, but the request was denied, the official remarking that "these physicians would say every call was a matter of life or death. The result would be that we would have a lot of doctors racing around town in automobiles and killing more people than they saved."

The Coronation Honor List.—The following are the medical men knighted and honored in other ways in celebration of the postponed coronation of Edward VII: Lord Lister has been made a Privy Councillor; Sir Francis Laking and Sir Frederick Treves have had baronetcies conferred upon them; knighthood has been conferred upon Dr. W. J. Collins, Mr. Alfred Cooper, Dr. J. Halliday Croom, Dr. Conan Doyle, Dr. Thomas Fraser, Mr. Victor Horsley, Mr. H. G. Howse, Mr. H. B. Longhurst, Professor William Macewen, Dr. Isambard Owen, and Professor Rücker; Sir William Church and Professor William Ramsay have been made Knights Commanders, and Major Ronald Ross and Dr. Whitelegge, Companions of the Order of the Bath; Lord Lister has also been appointed to the new "Order of Merit."

The Sloane Maternity Milk Set.—The name of the writer of the description of this apparatus in the Medical Record of July 5 was inadvertently omitted. The author was Dr. E. B. Cragin, 62 West 50th Street, New York.

Dr. Boleslaw Lapowski has been appointed attending Surgeon to the Skin Department of the Good Samaritan Dispensary in this city.

American Medical Association.—The date for the fifty-fourth annual meeting of this association at New Orleans has been set for May 5–8, 1903.

A Murderous Assault at the Foundling Asylum.—A man who was left in his infancy at St. Joseph's Foundling Asylum in this city and was brought up by the institution, has recently made much trouble by insisting upon being told his parentage. This being refused him, he went there a few days ago and shot two of the sisters—one, Sister Angela, slightly, but the other, Sister Cyrilla, very seriously. The latter was shot in the chest, but it is not known whether the lung was wounded or whether the ball is lodged in the muscles of the back.

The Late Dr. George F. Carey.—At a meeting of the Medical Board of the New York Foundling Hospital, held June 30, 1902, it was ordered that the following minute be inscribed upon the Hospital record: "The Medical Board of the New York Foundling Hospital regret the death of their colleague, Dr. George F. Carey. During his service of nearly thirty years as attending physician he was most regular in his attention, always showing the greatest interest in the children and in the affairs of the hospital. So far as it concerned himself, he was entirely disinterested. Active and energetic, he was successful as a physician, a careful and painstaking surgeon; a good teacher; of excellent attainments and of courtly manner. His daily life was that of a Christian, and he died as he had lived, with an unfaltering trust and hope of immortality, and this minute is placed on record, not because of duty and established custom, but because his gifts and qualities brought him the love and respect of those around him, and his death comes as a personal loss."

Thomas Darlington M.D.,
President.

T. Halstead Myers, M.D.,
Secretary.

Obituary Notes.—Dr. William Oliver of Penn Yan, N. Y., died suddenly at his home on July 10, of cerebral apoplexy. He was a graduate of the Geneva Medical College in the class of 1846 and had practised in Penn Yan continuously for over half a century.

Dr. John Reinoehl of Lebanon, Pa., was killed on June 11 by the running away of a horse he was driving. He was a graduate of the Medical Department of the University of Pennsylvania in the class of 1882. Dr. E. P. Marshall of Annville, who was with Dr. Reinoehl in the carriage, was seriously injured.

Dr. Charles A. Von Urff of Brooklyn died at his home in that borough on July 16, in his thirty-fifth year. He was a graduate of the Long Island College Hospital in the class of 1890.

Dr. Emmet F. Enos died at Elgin, Ill., on July 17, at the age of thirty-eight years. He was a graduate of Rush Medical College, Chicago, in the class of 1892. Dr. Enos was on the medical staff of the Kankakee Insane Hospital for five years prior to his resignation last February, when he felt his mind giving away. He diagnosed his own case and hoped by leading a quiet life his faculties would be restored. He engaged in medical practice in Herscher, but did not improve in health, and was soon forced to abandon it. The cause of the fatal illness was said to be a physical injury received many years ago.

Dr. James Elliott Dwinelle of Baltimore died suddenly on July 18. He was born in Cazenovia, N. Y., in 1830, and was graduated from the Jefferson Medical College in 1854.

Dr. Thomas Henry Hoskins died in Newport, Vt., on July 18 at the age of seventy-four years. He was born in Gardiner, Me. He was graduated from the Medical Department of the University of Louisville in 1853, and practised medicine in that city until 1861, when he removed to Boston. He retired from practice many years ago and devoted himself to agriculture, founding the *Vermont Farmer* in 1870.

Dr. Edward L. Parker, for four years one of the physicians of the Long Island State Hospital in Brooklyn, was drowned at Sea Gate on July 17. He was twenty-six years old.

Dr. Frederick B. White of this city died on July 18, aged thirty-one years. He was a graduate of the Medical Department of Cornell University in 1896.

Therapeutic Value of Work in Hysteria and Neurasthenia.—Sidney I. Schwab says that the work cure can be tried with the hope of success in that class of neurasthenic and hysterical subjects where there exists an average amount of potential physical vigor, where there is no organic nervous or other disease, and where, above all, there is found the requisite amount of intelligence and mental training to enable them to appreciate and understand the purpose and the meaning of the efforts made to hold them. In the author's experience he has found very few who might not have been treated in the manner indicated if the patient's circumstances and the patience of the physician had been used to their utmost. Monnier, from an experience of thirty-four cases, concludes that by means of useful manual work, hysteria and neurasthenia, in the narrowest sense of the term, can often be made to completely disappear. In cases of mental enfeeblement, psycopaths, alcoholics, according to the time of their existence, the influence of work is often very remarkable. Hypochondriacs and paranoiacs are not especially benefited. Schwab reports the case of a woman of intelligence, but suffering from aggravated hysteria, which it seemed impossible to overcome. Book-binding, which requires the closest attention and the greatest care in the matter of detail, and which is distinctly a fine art, was tried, and has proved to be the needed remedy. There is little doubt that in less than a year the previously hysterical invalid will be able to set up her own shop and lead a useful and active life.—*Interstate Medical Journal.*

Book Reviews.

A Manual of Toxicology. By Albert H. Brundage, A.M., M.D. New York: Henry Harrison Co., 1901.

The author has here given us a very convenient and handy little manual for either the pocket or the library table. He includes several hundred crude substances and their preparations that from time to time have produced symptoms of either acute or chronic poisoning. It is not, of course, a systematic treatise on toxicology, but just a little reference book that may never be needed, or, on the other hand, may prove just what is wanted in an emergency.

Quain's Dictionary of Medicine. Third Edition. Edited by H. Montague Murray, M.D., F.R.C.P., Lecturer on Medicine, Charing Cross Medical School, Assisted by John Harold, M.D., B.Ch.B.A.O., and W. Cecil Bosanquet, M.A., M.D., M.R.C.P. New York: D. Appleton & Co, 1902.

The third edition of this work is issued in a single large volume instead of two as formerly, and has been, in certain respects, abridged and condensed to suit the present conditions. In a general sense, this is an improvement, inasmuch as certain irrelevant material has been omitted and extra space given to more strictly medical subjects. This does not interfere with the general plan of the work, which is enclyclopedic in all essential particulars, and admirably well arranged for its purposes. A large number of new articles, bearing on special topics, have been added, and several graphic page plates have been inserted, which give a peculiar value to the work as a whole. An examination of the subject matter in detail shows commendable efforts on the part of the various contributors to keep apace with all the recent advances in pathology and practice which have characterized the period from the time that the previous editions were published. Leading features of the work are its admirable condensation of material, its systematic arrangement of subjects, and its judicious cross references admitting of such ready and satisfactory consultation. In these respects it is of special value to the practitioner and student, focussing an immense amount of accurate and practical information into a comparatively small focus.

Compend of General Pathology. By Alfred Edward Thayer, M.D., Assistant Professor in Gross Pathology, Cornell Medical College. Philadelphia: P. Blakiston's Son & Co., 1902.

This is an admirable compend of general pathology, and is thoroughly adapted to the practical needs of the student and general practitioner. The arrangement of subjects is systematic and natural and takes the reader from the general to the special forms of diseased action, explaining in due course the gross and minute pathology of each. More than this the explanations and descriptions are models of clearness, precision, and practical application.

Diseases of the Intestines. By John C. Hemmeter. Vol. II. Philadelphia: P. Blakiston's Son & Co., 1902.

We have not long ago reviewed and praised the first part of Hemmeter's work on the Intestines, and we can justly apply the same remarks to this volume. It is extensive, complete, and well written. Hemmeter advocates intestinal puncture in occlusion of the bowel, and gives his own experience with the following words: "My first experience with intestinal puncture occurred in connection with severe volvulus of the sigmoid flexure in a negro, aged forty-two years, and living in the mountains of western Maryland. The usual non-surgical means of replacing failed. I had used one-quarter grain of morphine subcutaneously with but transient relief, the meteorism was enormous. The only instrument I had with me was a hypodermic syringe, with the needle of which I punctured the most distended loop, after washing the patient's skin with soap and hot water. Gases escaped in large quantities; at the end of five minutes the intestine had not yet completely emptied itself. On the following day, when I arrived to give a large enema of warm salt water, every symptom of obstruction had disappeared and the man said he was well. Since then I have been compelled to employ the method in four other cases, partly because other therapeutic measures had been exhausted, operation refused, or because no other instrument but a hypodermic needle was at hand. Three of these four cases were types of sigmoid volvulus, the fourth an ileocæcal intussusception. I had every reason to believe that the puncture aided in restoring the bowel to its normal state. Whilst I am fully aware of the dangers of the procedure, and far from advising its application to every case, I can see no reasonable objection to it when performed by experienced hands in the first stage of intestinal occlusion, before intestinal paralysis has set in, and when peristaltic movements of the intestines may be plainly seen and felt through the abdominal walls, after the use of opium has been stopped for some time."

Health, Speech, and Song: A Practical Guide to Voice Production. By Jutta Bell-Ranske. London: Swan Sonnenschein & Co. New York: E. P. Dutton & Co., 1902.

It is a useless task to attempt to reconcile the various conflicting views put forth by singing teachers as to correct vocal methods. Each is, in the opinion of its advocates, entirely right and every other theory is entirely wrong. The author of the present work offers the familiar tale of long groping in the dark with unsatisfactory results and final emergence to the light (of her own views) which have effected a revolution in her teaching and in the results attained by her pupils. The book is crudely written and is extremely loose in its use of anatomical terms. To some of its statements positive objection can be made. Yet the author has apparently studied hard, and is to be especially commended for her recognition of the importance of the nasal mucosa with reference to proper breathing. In our opinion the greater number of vocal defects attributed to wrong vocal methods is due to the fact that the larynx of singers is usually a very much overworked organ. While ordinary conversation can be carried on indefinitely, constant singing cannot. More rest and less exercise will often be the best and quickest method of cure.

Progress of Medical Science.

The Boston Medical and Surgical Journal, July 17, 1902.

Empyema in Children.—F. J. Cotton, among other conclusions drawn from the data, says that the infection is usually with the pneumococcus. Spontaneous cure, even when aided by tapping, is rare. Operation should not be delayed, as time lost is strength lost, and the issue is largely one of nutrition. The best form of operation is, in general, the subperiosteal resection of an inch of the eighth or ninth rib in the posterior axillary line, the evacuation of pus and fibrin masses, and tube drainage. Irrigation is not usually advisable. The routine after-treatment in fresh cases should be tube drainage, the tube being progressively shortened, and removed when the cavity is nearly healed. Where failure to heal seems to depend on failure of the lung to re-expand, treatment by valve or suction apparatus is indicated. The great majority of the cases heal even when the healing is delayed for several months. The closure of the cavity depends mainly on nutrition and on adequate drainage.

The Influence of Alcohol upon Infection and Its Use in the Treatment of Acute Infectious Diseases.—S. J. Meltzer says that his defense for the use of alcohol in infectious diseases is that alcohol stimulates the patient by effecting a favorable distribution of the blood within his sick body, and protects him from harmful excitations by stimulating some of the normal inhibitory mechanism of the body. It is a noteworthy fact that among the opponents of alcohol there is not a single clinical man of note who has come out unqualifiedly against the use of alcohol based simply upon unfavorable clinical results gathered at the bedside. On the contrary, clinicians ranking high in the profession and thoroughly familiar with the pharmacology of the drug are unwilling to be deprived of its aid in dealing with diseases like typhoid fever or pneumonia. Personally, the author is willing to be responsible for the two following statements: Alcohol in health is often a curse; alcohol in disease is mostly a blessing.

A Report of Two cases of Typhoid Spine.—George Wilton Moorehouse reports two cases of this rare complication of typhoid, the literature of which, so far as he has been able to collect it, consisting of but fifteen articles describing twenty-one cases. He calls attention particularly to the occurrence of deformity and to the frequent association of fever with the affection. The prognosis of painful affections of the spine, so far as recovery is concerned, is excellent. The writer holds that the true type of the "typhoid spine" is a symptom complex due to an inflammatory process, and that pain in the back following typhoid fever, but due to other conditions, should not be confused with it. In the treatment relief from pain is the first requirement. This end may be obtained in some cases by rest in the recumbent position, or by mechanical devices, extension, or a jacket. Antirheumatic, sedative and hypnotic remedies may be employed, but unless the suffering is mild, opiates will be found necessary from time to time. Other medication seems not to be of any great value.

Journal of the American Medical Association, July 19, 1902.

The Treatment of Yellow Fever. After an historical review, James Carroll considers this question in the light of our present knowledge. He believes that in previously healthy subjects, free from organic lesions, the mortality can be practically reduced to zero. The primary indication is to remove the toxin. This is best done through the kidneys, aided by a moderately free action of the skin and moderate depletion by saline cathartics. Hot mustard foot-baths, sinapisms to the stomach, cold cloths to the head, saline enemas with sodium sulphate solution, are all indicated. For the first three days only milk with vichy or lime water should be given. Iced champagne is permissible. Other treatment follows along symptomatic lines. The author suggests that urea taken by the mouth or injected under the skin may serve as a valuable diuretic.

The So-called "Spotted Fever" of the Rocky Mountains. In a preliminary report to the Montana State Board of Health, L. B. Wilson and W. M. Chowning state that they could find in this disease no bacterium standing in a positive etiological relation. Staphylococci of different varieties were found in the skin, and B. coli communis in cultures from the spleen. The latter organ showed in one case a special anærobic putrefactive bacillus. So also several protozoa were present, some of which apparently found their habitat in the red blood cells. The prevailing protozoon resembled the pyrosoma bigeminum of Texas fever. Apparently, spotted fever belongs rather to the latter type of disease than to the malaria group. The most probable theory as to the mode of infection ascribes the latter to tick-bites. The extreme isolation of cases of spotted fever, their occasional development in localities removed many miles from the site of any previous case, and the long period existing between the death or convalescence of the last case of any one year before the development of the first case in the following year, would point to the possibility of the red blood cells of some one of the lower, warm-blooded animals being the normal habitat of the parasitic protozoon in that stage of its life cycle not passed within the body of some arachnid. Of the animals within the infected region, the common gray gopher would probably best fulfill the conditions of such a parasitism.

Ulcer of the Bladder.—L. E. Schmidt would classify these ulcers in a general way, as follows: (1) Gonorrhœal (the most common); (2) Traumatic; (3) Those following a non-gonorrhœal cystitis; (4) Tuberculous; (5) Those following necrosis of malignant tumors; (6) Solitary; (7) Perforating, and (8) Syphilitic. The traumatic variety arises from a calculus or foreign body, possibly from instrumentation. Cystoscopy alone enables an accurate diagnosis to be made. Treatment by irrigation is ineffective. It is absolutely necessary to curette, to remove the coating and the granulations on the base. It is highly desirable at the same time to apply the thermocautery over the curetted area—partly to stop any hemorrhage, which, however, is usually of a light character, and also to cover the curetted field with a protective eschar. In the course of generalized ulceration of the bladder of non-gonorrhœal cystitis, this method of treatment is worthless. In these cases the only thing to do is to open the bladder and curette the entire affected mucosa. In this way all the diseased tissue is removed by the curette and the bladder is put to rest by the temporary drainage. The infiltrated walls thus become less swollen and lose their œdematous condition, without being irritated from distension. If the condition which is called cystitis dolorosa has set in, the parts must be thoroughly curetted and the bladder completely tamponed. The tamponade must be kept up until the walls of the bladder have lost their sensitiveness, for if it is stopped previously to this, the affected areas will come in contact with each other and the entire process be repeated. In cases of solitary tuberculous ulcerations and infiltrations (nodules) it is possible to get perfect results with the use of the cystoscope. These ulcerations and infiltrations can be completely and thoroughly curetted and then cauterized. If the infection of the bladder arises from a tuberculous kidney it naturally follows that previous to any endovesical procedure it is necessary to remove the source of infection by a preliminary operation on the kidney or ureters or both.

New York Medical Journal, July 19, 1902.

The Early Diagnosis of Uterine Cancer; Operative Limitations. J. O. Polak says that the early diagnosis of uterine cancer is possible. The earliest symptoms differ, depending upon whether the disease begins during menstrual life or after the menopause. During menstrual life every bleeding should be compared with the ordinary menses in the same woman, and the physician should be suspicious of intermenstrual spotting and serous discharge.

After the menopause any serous or sanguineous discharge is significant. Every woman over thirty who may exhibit any menstrual vagary or persistent leucorrhœa should be examined. Radical operations should be limited to those cases in which the disease is confined to the uterine tissues.

On the Contraction of the Ilio-Psoas Muscle as an Aid in the Diagnosis of the Contents of the Iliac Fossa.—The ways in which elevation of this muscle during its contraction may aid in diagnosticating the contents of the iliac fossa are, according to S. J. Meltzer, the following: (1) It can be used as a landmark. It is often very helpful to know whether a certain painful spot or a palpable resistance is located on the psoas or on its lateral or its median side; (2) The elevation brings the viscera above it nearer the surface and nearer the palpating fingers. By this aid the outlines of the viscera are often much more distinctly ascertainable than under the usual palpation; furthermore, the usual resistance of the contracting abdominal muscles is often considerably lessened while the thigh is moderately flexed; (3) The outlines of the viscera are more easily palpable when they are moved under the fingers while riding on the elevated back of the psoas than when they are flatly stretched on the even surface of the iliac fossa; (4) By repeatedly increasing and decreasing the flexion of the thigh the viscera move to and from our fingers and sometimes render to palpation an assistance similar to that which it derives from the respiratory movements; (5) When the active flexion approaches a right angle, the viscera can often be felt moving perceptibly headward on the steep slope of the psoas elevation. The movement is absent when the viscus is adherent; (6) By alternate abduction and adduction of the thigh while in a flexed condition the psoas elevation moves from side to side and assists the palpation in many ways.

The Histrionic Element of Mental Disease.—In this paper T. H. Kellogg refers to those patients who imagine themselves to be various great personages, either real or imaginary. The disturbance may take the form of some single passion, love, jealousy, erotomania, etc., or may show itself in disjointed bits of theatrical behavior. The clinical facts and conclusions of the paper may be presented as follows: The histrionic element in mental disease is the direct outcome at times of irresistible impulses and outbursts of emotions. It results at other times from terrific delusions and hallucinations, which impel the sufferer to tragic acts. It proceeds in some cases from a central and organized false belief, which leads to sensational monomaniacal rôles. Again the theatrical phases develop from morbid love, jealousy, or other overwhelming passion, or from actual changes of personality peculiar to insanity. The histrionic element taking the form of caricatures and mimicry is an aberrant manifestation of the law of imitation, which is so fundamental in all formative mental processes. As a matter of clinical fact, the histrionic performances are spontaneous and involuntary in some patients, attended by slight deliberation and self-control in others, and in a few cases directed by the most perverse wilful intent and insane cunning. The recognition of this histrionic element as an integral part of mental disease throws light on some obscure phases of mental pathology, clears up the puzzling nature of cases seemingly mixed of sham and reality, and also has practical bearing in the prognosis and treatment of mental maladies.

Medical News, July 19, 1902.

Hepatic Gout and Its Treatment.—J. Leffingwell Hatch says that there is a certain form of hepatitis due to excess of uric acid in the blood; this is the result of defective metabolism, and, when a certain limit is reached, toxæmia results. After this follows a nervous explosion with symptoms of headache, vertigo, vomiting, wandering pains, cramps, trembling of the limbs, fever, etc., which fully justify us in classifying it among the rheumatic manifestations under the name of hepatic gout; this is amenable, like other manifestations of this class, to treatment by administration of colchicine and salicylic acid, and complete removal of the symptoms may be effected if this be persistently carried out.

The Non-Heredity of Acquired Characters.—Lawrence Irwell states that we do not know how congenital variations originate. There is no more knowledge as to what the first case of alcoholic susceptibility was due than there is of the origin of supernumerary fingers. Both are undeniably hereditary. The man born with the alcoholic diathesis becomes a drunkard, unless withheld by moral or other deterrents. But the acquired taste for alcohol is not passed on to the next generation. The vast majority of drunkards are persons who were born with a brain and a nervous system of poor quality, and narcomania in any form is merely the outward manifestation of the disease. As to pseudoheredity, a typical case is the following: A parasitic larva, living upon a tree with few leaves, develops into a small and stunted imago. It has not inherited its abnormality from the tree, nor could it inherit anything from the larva, for it is the same insect in a different stage. The problems of heredity are very intricate and cannot be summarily dismissed, because, upon superficial examination, certain conditions seem absurd to those whose knowledge of biology is limited. A parent transmits not himself and all his acquired modifications, eccentricities, and tendencies, but merely the representative constituents of which he is both a product and a custodian. His influence over his reproductive elements is little greater than is that of the host over the parasite. According to Galton, "acquired modifications are rarely, if at all, inherited in the correct sense of the term."

Is Vivisection a Benefit to Animals and Man and Justifiable?—E. Stuver reviews the beneficent results which have come from scientifically applied experimental investigations on living animals. As to those who depict the sufferings in experiments on animals, more real knowledge and less sentiment would be an inestimable gain to both themselves and to humanity. For example, since the motor region of the brain is insensitive, the operations on these parts of the brain substance do not cause any pain whatever. The writer admires the zeal and enthusiasm of the antivivisectionists, but it is strange that they should so bitterly oppose those agencies which have done so much to make the world brighter and better, while they allow much greater evils to go on unheeded. For example, if the useless slaughter of birds which are used for the ornamenting of bonnets could be stopped, more suffering would be prevented than is inflicted by all the scientific experiments in existence. There are thousands of animals that are yearly wounded and mutilated for the recreation and amusement of the leisure class. Another method of alleviating suffering would be to stop the chase where defenseless creatures are run down by horse and hounds, simply in the name of sport. Still further, there are thousands of women and children who are dying of slow starvation in our cities who should be rescued. If attention were turned into all these channels, much good would be done, while the welfare of humanity, as well as the best interests of the lower animals, would be protected and advanced by physicians and scientists, as they always have been in the years gone by.

American Medicine, June 19, 1902.

A Rare Fracture.—The case here reported by Angus McLean was that of a man aged thirty-six years. While walking on an icy street, he slipped. He did not fall, but felt something about his thigh snap. He was treated by his physician for rheumatism. He had been able to walk after the accident, although he felt some pain in the upper, internal femoral region when moving the leg in certain directions, and some soreness of the muscles. About six months after the injury, a swelling developed in the upper inner surface of the thigh, with some fever. This swelling was opened and a piece of bone 1½ inches long was extracted. It was discovered that the pubic arch was not intact. The bone was a piece of the descending ramus of the pubis and ramus of the ischium. The fracture was due to the action of the adductor muscles.

A Case of Severe Anæmia Caused by the Uncinaria Duodenalis.—A. B. Herrick has followed up the history of this case. The patient was born in Germany. The present illness began with an attack of diarrhœa. The case bore a marked resemblance to pernicious anæmia in the peculiar pallor manifested, the retention of the adipose tissue, and the remarkably low blood count with leukopenia. The eosinophiles amounted to 26.8 per cent. An examination of the stools cleared up the case, for numerous typical ova of antkylostoma were present. After thymol was given about sixty adult worms were found. They were the old-world hookworm. There were no nucleated red cells in the blood, and that and less marked poikilocytosis and the presence of eosinophilia were the points in the blood examination showing the difference from pernicious anæmia. The patient was rapidly improving at the time the report was made.

Ankylostomiasis in an Individual Presenting All of the Typical Symptoms of Pellagra.—H. F. Harris reports this interesting case. The patient, a man of twenty-nine years, lives in Georgia. He has been brought up in great poverty. His bread has always been prepared from Indian corn, which has formed the greater part of his diet. The first symptoms usually begin in the spring with loss of appetite, thirst, and a feeling of malaise. He suffers from melancholia. His legs become extremely weak, and sensation to pain is far below normal. In the spring his hands, arms, and the dorsal surfaces of his feet become greatly inflamed. Blisters form, followed by scabs.

He suffers from constipation, and has a great distaste for food, especially for Indian-corn bread. During these periods he has constant pain in the neck and tenderness and pain in the gastric region. He vomits frequently. He begins to improve after May or June and by July or August is generally well again. The patient has all of the typical symptoms of pellagra. If this is a genuine example of the disease, it is the first case of the kind that has been reported in the United States. In the man's fæces, numerous eggs of the ankylostoma have been found, and it seems not unlikely that the pathologic condition is in large measure due to this cause, but on the other hand there are certain features that are not consistent with this explanation, such as the strange tendency of the disease to manifest itself only in the spring and early summer, and the fact that it has existed for fourteen years. These parasites are said not to live in the body for more than five or eight years at the very outside, and unless the patient has been repeatedly reinfected, the presence of these parasites cannot entirely explain the long duration of the disease. Thymol was recently given to the patient, and not less than 600 worms passed from the bowels. No eggs of the ankylostoma were found four weeks after the treatment. The patient, however, is now feeling no better than before. If he has pellagra, the disease is so far advanced that nothing probably could be done for him. He has been advised to go to a cooler climate and to be careful not to eat decomposed Indian corn. It should be noted that the blood examination showed the hæmoglobin to be only 20 per cent., the red cells, 1,760,000, and the white cells, 4,020; there was decided poikilocytosis.

The Philadelphia Medical Journal, July 19, 1902.

Hemorrhagic Infarction of the Kidney, with Report of a Case.—George P. Dale states that in this affection the patient will usually give a history of previous heart disease, and the symptoms on the part of the kidney are ushered in by a sudden severe pain in the lumbar region, with possibly a chill, followed by a dimunition in the amount of urine. The urine soon contains blood, varying in amount with the extent of renal disturbance. The patient whose case is reported was an Irish girl of twenty-one years. She was suffering, when seen, from shortness of breath and pain in the right lumbar region and back. The pulse was very irregular, weak, and of low tension. The heart showed such irregularity of action that it was difficult to distinguish the rhythm of the murmur. The apex beat was forcible in the sixth interspace, outside of nipple line, and the impulse was diffused over considerable area. Palpation in the right lumbar region caused much pain. The patient was put to bed and at first given salts. This was followed by diuretics. About six months later, after having gone away from and returned to the hospital several times, the patient's condition was fairly good. Examination of the urine at the time of admission to the hospital showed a large amount of albumin, blood cells, pus cells, and granular and epithelial casts. This case shows how severely the heart and kidneys may be disturbed and the patient still continue to live and even work.

Recent Progress in Prostatic Surgery.—G. Frank Lydston gives the following points which he says ought to be impressed upon the prostatic: (1) If palliative measures, instituted at a relatively early period, do not inhibit the development of prostatic overgrowth, a slow but sure increase of the enlargement is inevitable and a change in the conformation of the prostatic urethra, with obstruction of the urinary way, is almost certain; (2) The time will inevitably arrive when he will be compelled to take his choice between the habitual use of the catheter, which will almost of necessity shorten his days, and a radical operation for the relief of the prostatic obstruction; (3) Early operation, before the occurrence of septic and obstructive changes in the urinary way, which always develop sooner or later, is comparatively safe, the reverse being true when he is faced with an operation of necessity. The guiding principle in prostatic surgery should be: Early diagnosis, followed in some cases by judicious means of palliation or of prophylaxis of permanent change of the prostate, and, failing of success with these measures, a radical operation—prostatectomy. The suprapubic method was until recently the most popular form of operation. The author likes, however, in suitable cases, the perineal method of prostatectomy, the principle of which is the same as that of the old perineal prostatectomy of Dittel. The Bottini operation, modified as the author suggested, by operating through a perineal incision, is a more rational procedure than the Bottini operation proper. The rational surgery of the prostate demands an early radical removal of the tissue overgrowth, which is the essence of the disease.

The Lancet, July 12, 1902.

Sodium Cinnamate in the Treatment of Tuberculosis.—O Ambein gives his results with this remedy, for the years 1899-1901. It acts by the induction of leucocytosis, thereby leading to an encapsulation and final cicatrization of tuberculous foci. Ambein has never observed any harmful effects following its use, though cutaneous pruritus followed in one case after every injection. The initial dose is one millegram (0.001). Injections are made every third day in increasing dosage. The maximal quantity being twenty-five millegrams. The author is frank enough to say that he has never seen any positively good effect which he could not satisfactorily (to himself) account for by the accompanying climatological, hygienic, and dietetic treatment.

The Subcutaneous Injection of Cinnamate of Sodium.—Lovell Drage calls attention to the fact that injections of cinnamate of sodium into the veins produces a general leucocytosis, by stimulating the simpler leucocytes to transformation into polymorphonuclear cells and intermediate forms. He has employed it in 10 per cent. solution in glycerin in pulmonary tuberculosis, cancer of the pancreas, inflammatory trouble about the middle ear, and tuberculous laryngitis. Injections have not exceeded thirty minims in amount. The results of the treatment he considers most promising. There may be many other substances capable of producing like effects. He feels some degree of assurance that the lines upon which diseases, such as cancer and tuberculosis, can be treated successfully are those based upon the principal of administering drugs which by their action on the white cells will assist repair in the cells damaged. In a note by G. T. Morgan is given a full description of the proper method of preparing the solution.

An Explanation of the Cause of Inequality of Pupils in Cases of Thoracic Aneurysm.—This question has been studied by R. C. B. Wall and E. W. W. Walker, whose conclusion is that the pupillary inequality observed in thoracic aneurysm is usually due to inequality of the blood pressure in the ophthalmic arteries, resulting from abnormal vascular conditions. A general summary of their line of argument is as follows: *A.*—The explanation which ascribes the anisocoria at times occurring in cases of thoracic aneurysm to interference with the sympathetic is unsatisfactory. 1. On anatomical grounds: (*a*) because in the majority of cases there is no evidence of implication of that portion of the sympathetic nerve trunk containing pupil dilator fibers; and (*b*) because it is not established that sympathetic filaments supply the sac wall of an aneurysm. 2. On physiological grounds: (*a*) because the explanation supposes that the same conditions may produce sometimes irritation and sometimes paralysis of the nerve; (*b*) because cases are rare in which there is any evidence apart from the pupillary change that the sympathetic is involved; and (*c*) because the pupillary changes are not those met with in cases where the sympathetic is involved. *B.*—1. Alterations in vascular conditions may be associated with alterations in the size of the pupils. (*a*) High arterial tension is associated with small pupils; and (*b*) low arterial tension is associated with large pupils. 2. The physical explanation of this phenomenon is probably to be found in the spiral structure of the vessels of the iris. *C.*—Local inequalities of blood pressure may therefore be associated with inequalities of the pupils. (*a*) Clinical evidence: 1. Enlargement of pupils is frequently associated with diminution of the temporal and radial pulses on the same side of the body. 2. Obstruction of the carotid artery on one side of the neck is associated with enlargement of the pupil upon the same side. (*b*) Experimental evidence: 1. Obstruction of the carotid in rabbits is associated with enlargement of the pupils on both sides, owing to the freedom of circulation at the base of the brain. 2. Injection of water into a carotid artery of a dead rabbit causes narrowing of the pupil upon the same side. 3. Digital compression of the carotid artery in the human subject is associated with enlargement of the pupil upon the same side.

British Medical Journal, July 12, 1902.

On Some Results Obtained by Disinfection and Isolation against Cholera.—Marc Armand Ruffer and C. Zachariades Bey describe the method of caring for the pilgrims at Tor. All pilgrims are quarantined for fifteen days at Tor. They are landed in batches of about forty. All articles requiring disinfection are immediately removed. The pilgrim himself is washed with warm sea-water. Any one with a pulse of over eighty is stopped and his temperature taken. The cholera patients are placed in wooden barracks containing two patients each, and so arranged that any side can be opened at will. The linen from the cholera section of the hospital is always steamed before being washed. The disease did not extend to any of the hospital staff or the cordon of soldiers, and no cases occurred on board ship after leaving Tor. All ships were thoroughly disinfected at Tor. There was a plague of flies at the time, but in spite of this the disease did not spread in the camp. This fact has raised a doubt as to the supposed rôle played by these insects in carrying cholera.

An Epidemic of Dengue Fever.—F. O. Stedman makes the interesting observation that although dengue is undoubtedly highly infectious, still there have occurred many instances in which there was only one case in a house in which there were many residents. The onset is quite sudden. Pains in the joints, with shivering and fever, often usher in the disease. Sometimes there is vomiting. An initial rash appears in some cases. There is then a certain amount of œdema of the skin. On the fourth or fifth day from the onset the terminal rash makes its appearance. This generally lasts for about twenty-four hours and then quickly disappears. Convalescence is then established in many cases, while in others there are various sequelæ. The first is the liability to relapses of fever. Malarial parasites are often found in the blood at this time. In certain cases there is a recrudescence or a continuance of the pains. These may be severe. The disease will run its course in any case. Sodium salicylate does something to relieve the pain and to keep the temperature within bounds. A hot bath often gives relief. The after pains are often obstinate. Salicin and potassium iodide have been used. Massage and stimulating liniments are useful. Some cases seem to defy all treatment, and the pain just dies away of its own accord.

The Treatment of Typhoid Fever.—N. E. Norway has treated about forty cases by his method, and has never lost a case. In his examination of the organs of typhoid patients after death he was struck with the fact that in no case did the food in the stomach or intestines appear to be digested. The cause of death in many cases seemed to be starvation. He says that the patient wastes because the food assimilated does not equal the elimination of urea and carbon dioxide, and this non-assimilation of food is in some way due to Eberth's bacillus. The bacillus being safe from direct attacks of drugs, there remains nothing to do but to strengthen the resisting powers of the patient. The writer, in view of these facts, makes use of the following mixture: Essence of pepsin, $\frac{1}{2}$-1 drachm; dilute nitrohydrochloric acid, 10 minims; glycerin, 20 minims; water, $\frac{1}{2}$ ounce. The half-ounce is put in half a tumbler or more of water, and is to be sipped as desired to relieve thirst. A dose every hour at first is given with ten minims of chloroform if the heart needs stimulation. A few minims of morphine hydrochlorate may be given if pain or want of sleep require it. As the temperature falls, as it generally does on the second or third day of the treatment, the dose is lessened. The mixture is given throughout the illness. Sometimes treatment is begun with 1 grain of calomel and 10 grains of phenacetin. The diet consists, as far as possible, of milk, unboiled. The flavor is varied by means of coffee or tea. Beef tea is given now and then, and later, the diet may be gradually increased.

Deutsche medicinische Wochenschrift, June 26, 1902.

Trichocephalus Dispar.—E. Becker reports two cases in which this parasite was responsible for the clinical picture produced. From a review of these, together with the cases hitherto reported by other observers, it is evident that three different clinical conditions may be produced by the trichocephalus, as follows: (1) That in which intestinal symptoms predominate. Here there is present severe diarrhœa, marked abdominal pain, intestinal hemorrhages, and vomiting. In some of these cases the symptoms closely resemble those of peritonitis or perityphlitis; (2) That in which the nervous system is principally involved; these cases are sometimes fatal and frequently show all the typical signs of a meningitis; (3) That in which the symptoms are chiefly hæmatogenous in character and correspond with those of a severe anæmia.

Venous Thrombosis in Acute Articular Rheumatism.—A. Hess reports two cases. In the first case, ten days after the commencement of the rheumatic attack and while this was still well developed, symptoms of thrombosis of the inferior vena cava and common iliac vein appeared. The legs soon became œdematous and considerable ascites developed. The general condition become very bad, and the end was only regarded as a question of time. Contrary to all expectations, however, after a short time the patient began gradually to improve, and in about four months all the symptoms had disappeared. The second case was fatal, and upon autopsy showed thrombosis of the superior vena cava and the left jugular and subclavian veins. These cases are of interest on account of the size of the veins involved, for while numerous instances have been reported in which acute articular rheumatism has been complicated by thrombosis of the smaller veins, only occasionally have cases been reported in which the larger veins have been implicated.

Berliner klinische Wochenschrift, June 30, 1902.

Folliculoma Malignum Ovarii.—Sigmund Gottschalk's patient had suffered with abdominal symptoms for about six months. The pain was severe in the left ovarian region and ascites was marked. Upon examination a tumor of the left ovary was detected and an operation for its removal was undertaken. Upon removal the tumor weighed about 250 gr. and was of the consistency of a soft myoma. Upon cut section the tumor was seen microscopically to consist of a parenchyma and stroma and to contain many pigment bodies. On the basis of the microscopical examination the author classes the tumor as a "folliculoma malignum ovarii. The chief clinical peculiarity observed in this patient was the large amount of ascites in comparison with the small size of the tumor, and the author is inclined to regard this characteristic as of diagnostic importance.

Münchener medicinische Wochenschrift, July 1, 1902

Wandering Heart.—Leusser describes under this name those cases in which the position of the heart within the thorax is subject to abnormal variation, such not being due to pathological alterations in the surrounding tissues. This change of position is easily demonstrated by locating the situation of the apex beat in different postures of the body. Having determined the location of the apex beat when the patient is in the upright position, he is then placed in the horizontal position on his left side, and the change in the location of the apex beat noted. Under these conditions in normal individuals this is never moved toward the left more than 2 cm., and if this is exceeded. a diagnosis of wandering heart may be made. Out of 400 persons examined by the author in six a wandering heart was found. Such persons usually show symptoms of palpitation, but are otherwise perfectly healthy. The name "cardioptosis" is also proposed by the author for this condition.

Infrequent Cases of Migraine.—Pässler reports three cases of migraine in illustration of features of this disease, which are of unusual occurrence. The chief interest concerning the first case relates to its etiology. The patient was a perfectly healthy young man, who first developed attacks of migraine after having received a fall upon his head. The attacks at first were somewhat indefinite in nature, but soon became typical in character. Hitherto very few cases have been reported in which the origin of the disease could be directly traced to traumatism. The second case showed, during some of the attacks, vasomotor disturbances, a bilateral dilatation of the pupils and a non-reaction of the pupils to light. It is interesting to note that in those attacks in which the vasomotor disturbances failed the eye symptoms were also absent. The third case was characterized by disturbances of motion, which closely resembled those seen in cerebellar ataxia; the tendon reflexes were also markedly increased. The principal treatment in this case was quinine, from the administration of which some benefit was produced.

Pathogenesis of Acute Articular Rheumatism.—Kollman considers the contagiousness of acute articular rheumatism, and reports an instance from which it might be inferred that this disease is directly or indirectly transferable. The patient was a male, twenty-nine years of age, and had frequently suffered from rheumatic attacks. During one of these attacks he was attended by his mother (fifty-four years of age), who had never had the disease. During the attack the woman slept at night under blankets which had covered the patient during the day, and which were more or less moistened by his perspiration, no sheets having been used. After the son had recovered the mother developed a typical attack of acute polyarticular rheumatism. The author believes that while there is some evidence furnished by this and other cases to show that acute articular rheumatism is contagious, that nevertheless great caution should be observed in accepting such a theory, since for the development of this disease many obscure factors are undoubtedly in some measure responsible.

French Journals.

Fibroma of the Uterus Compressing the Ureters.—Dauvergne reports the case of a woman who had had a uterine fibroma for about eight years. A few days before her entrance to the hospital she showed signs of partial anuria, which occurred suddenly with symptoms or uræmic intoxication—dyspnœa, vomiting, etc. The patient was catheterized, and about 150 grams of very dark urine with a thick deposit of albumin were obtained. There were no red blood cells, nor any abnormal elements. Total abdominal hysterectomy with removal of the adnexa was performed. The day after the operation there was no albumin, and vomiting had ceased. The condition had probably occurred in this way: The kidneys, distended for a long time by compression of the ureters, were attacked by interstitial nephritis, just as when the ureters have been incompletely ligated. This lesion is often slight. It often remains latent for some time. Then congestion of the kidneys develops, characterized by marked albuminuria.—*Gazette de Gynécologie*, June 1, 1902.

Bucco-Nasal Respiration Is Possible. H. Lavrand says that bucco-nasal respiration is possible; it completes insufficient nasal respiration during an exercise which causes panting. It takes place: (1) When the mouth is slightly gaping, for the tongue is not too much depressed, and the pharyngo-buccal canal not too large proportionally to the pharyngo-nasal; (2) When at the same time the veil of the palate is not contracted, so that it hangs between the tongue and the posterior wall of the pharynx, it divides, then, the current of air expired, as that which passes through an organ pipe; (3) Like expiration, inspiration can take place by the nose and mouth simultaneously; (4) The so-called intra-buccal vacuum of Donders does not exist ordinarily, but is produced only by suction.—*Journal des Sciences Médicales de Lille*, June 21, 1902.

Secretion of the Sub-maxillary Gland after Resection of the Cervical Ganglion of the Sympathetic.—Malloizel sums up these results which have been observed after resection of the superior ganglion: (1) The various excitants, such as meat and salt, call forth the saliva which is appropriate for them—viscous for meat, liquid for salt, as in a normal dog; (2) The quantity of saliva secreted is the same as in a normal dog; but the saliva is always a little richer in mucin than normally; (3) Atropine, in a small dose, suppresses all salivation in the dog. The chorda tympain alone can then provoke the different salivary secretions adapted to different aliments. On the other hand, the sympathetic has an action, since the saliva is more rich in mucin when it is cut, and atropine suppresses all secretion when it is not performing its function.—*La Médecine Moderne*, June 25, 1902.

A Note on Adrenalin.—Ch. Amat states that of all the vasoconstrictors adrenalin is the most active one that is known. The intravenous injection of this drug has a very powerful action on the nervous system, especially on the muscular walls of the vessels. Blood pressure is increased, sometimes enormously. Adrenalin is a powerful hemostatic, acting promptly from two to three minutes after its application to the mucosa, its effect lasting from twenty minutes to four hours. It rapidly alleviates pain in all forms of keratitis, iritis, and even in glaucoma, where it reduces the ocular tension, thus preventing hemorrhage in iridectomy. The opacities of the cornea, consecutive to contusions, are promptly cleared up by adrenalin, which also appears to modify favorably the opacities of keratitis in syphilitic iritis. Adrenalin will also reduce the swelling of the lacrymal canals, and allow the passage of liquid, thus avoiding the necessity of using a sound. Certain buzzings in the ear are relieved by the introduction of a drop of the solution of adrenalin into the Eustachian tube. Adrenalin is as valuable a therapeutic agent as cocaine.—*Bulletin Général de Thérapeutique*, June 23, 1902.

Cyclic Vomiting of Autoinfection, and Its Treatment.—Bernard R. LeRoy advises against the hypodermic use of atropine and morphine in this affection. Whatever is done for the patient must be done in the early stages of the disease, or else it is safer to let the disease run its course. The author has found that to give a remedy that would act on the small intestine quickly, kindly, and with certainty would be the ideal prescription. This he has found in the following: Pulv. myrr. et aloes ʒii, pulv. guaiaci ʒjss, pulv. capsici ʒj. M. Triturate in a porcelain mortar to an impalpable powder and add Ol. cinnamomi gtt. xxv. M. Fiant capsulæ No. xxv. Sig.: A capsule every four hours until the bowels act in a free manner. He gives no other medicine, but regulates the dose and the frequency of administration to suit the strength and the resistant powers of the patient. He supplies his patients with the medicine, with instruction to take as directed at the very onset of the attaeck.—*The Therapeutic Gazette.*

Therapeutic Hints.

Migraine is probably of toxic origin. Brain workers and those following sedentary occupations exhibit the most cases, pointing to the probability of a passive portal conjestion. This leads to fermentation in the intestines and absorption of toxic products. The hereditary character in these cases is referred to the intestinal condition. The treatment is therefore toward the restoration of the general tone of the nervous system, developing the muscles, improving the abdominal circulation, and, so far as drugs are concerned, administering intestinal antiseptics and cathartics. The mercuric laxative should be given at least once a week. This should be a 5-grain blue pill at night, followed by a saline in the morning. Also one or two drachms of sulphate of soda with gr. 10 of salicylate of sodium in a tumbler of warm water is to be given every morning. Also one half hour before each meal a pill containing one half grain of bichromate of potassium, and after meals bismuth subcarbonate. At night a full dose of an intestinal antiseptic, phenol bismuth or ammonium benzoate or sodium benzoate, gr. 10 given in two capsules. W. J. THOMPSON.

Urinous Smells.—Cases in which there is dribbling of urine in the bed, attended by the usual disagreeable smell, can be made less obnoxious by pouring some turpentine upon the sheets, where it will not touch the patient's skin. This counteracts the odor to a remarkable degree.—*International Journal of Surgery.*

Dressing the Umbilical Cord.—Wrap the cord in a piece of cotton soaked in alcohol. This is at once a germicide and causes rapid drying. BULLBERG.

Carbolic-Acid Poisoning.—Give at once a large dose of alcohol—whiskey, brandy, rum, or gin will do; and the dose should be repeated often.

Ginger.—Ginger is a remedy commonly overlooked when a stimulant is needed. It is more popular in domestic practice than with the profession. Its stimulating is instantaneous and greater even than alcohol. It has pain-relieving qualities which are difficult to explain. Whenever there is a sudden reduction of temperature, with coldness of the skin or extremities, or chilliness, all accompanying some severe local pain, this agent is specific.

Boils.—Oxygen under pressure is introduced into boils and carbuncles, by means of a Provoz needle and pump. The pain diminishes very rapidly, and the next day there is a noticeable change. In a few days cicatrization takes place. THIRIAR.

Pneumonia in Young Children can be diagnosticated from other diseases by the following sign: There is a lack of expansion of the subclavicular region independent of the location of the pneumonia lesion. On placing the fingers upon the subclavicular region they are lifted as by a wave on the sound side, while on the other the lack of expansion is evident even in early stages of the disease. In pleurisy and pneumothorax the lack of expansion corresponds with the site of the lesion. WEILL.

Klopfen Tuberculosis Cure.—This method consists in slapping with a silver paper cutter the surface of the chest, in front, behind, and at the sides. A scientific examination of the advantages said to result from this process appears to justify the conclusion that it is really a means of powerfully stimulating the pulmonary apparatus and of dissipating the tendency to congestion, and in this manner promotes spontaneous healing of tuberculous lesions.

Incompatibilities.—According to the *Journal of the American Medical Association*, chemical incompatibility may be apparant in three ways: (1) By precipitation or formation of insoluble compounds; (2) By evolution of gas; (3) In some instances by change of color in the mixture. The largest class is included in the formation of insoluble compounds by precipitation. This takes place when two salts combine and form an insoluble salt by interchange of radicals. The most important incompatibilities are included in the following table, arranged alphabetically by M. L. Neff, for the convenience of the practitioner: (1) Acids or acid salts are incompatible with alkalies or alkaline salts, alcohols (tinctures) and glycerin, hydrates and carbonates, glucosides, bases, relatively weak or volatile salts; (2) Alkalies with alkaloids and their salts, chloral, acids and their salts, relatively weak salts (halogens), metallic salts, calcium and magnesium salts; (3) Alkaloids and their salts with alkalies, alkaline salts, halogen, salts, tannic acid, phosphoric acid, boric acid, borates, hydriodic acid, carbonic acid and carbonates; (4) Arsenic is incompatible with tannic acid, salts of metals, especially lead and silver; lime, magnesia; (5) Aqueous solutions are incompatible with chloroform, metallic salts, essential and fixed oils; alcoholic tinctures, fluid extracts, resinous tinctures; (6) Calomel with antipyrin, alkalies, iodide of potassium, salt of iron and lead; (7) Carbonic acid and carbonates with iron salts, metallic salts, salts of calcium and mg. 'aceti acid; (8) Lime water with salts of mercury, carbonates of alkalies, morphine and quinine salts; (9) Mucilage with alcohol and nitrous ether, iron, aq. plumbi and mineral acids; (10) Nitrous ether with tinct guaiac, mucilages, antipyrin, puri sulphus, most carbonates; (11) Oxidizing agents; including permanganates, chlorates; nitrates with charcoal, ammonium chlorid, tannic acid, sulphur, glycerin; (12) Phosphoric acid and phosphates with alkaloids, metallic salts, salts of magnesium and calcium; (13) Tannic acid with alkaloids, metallic salts, arsenic, digitalis, albumins, gelatins; (14) Gentian preparations with iron salts, infus. prunes virginianæ, inf. chinconate comp., silver nitrate, lead salts.

Etiology of Recurrent Icterus Graviditatis.—O. Schaeffer considers, as exemplified by a case within his observation, that form of icterus which occurs exclusively during pregnancy and is not dependent upon disease of the liver or other organs. Beginning with the second half of pregnancy the nutritional demands of the fœtus require a marked increased supply of lime salts. The red blood-cells constitute one of the principle sources of such salts. Under normal conditions comparatively few red blood cells are destroyed in this process. Observation has shown that in cases of icterus graviditatis the red blood cells are markedly reduced in resistance. This may be easily demonstrated by their tinctorial and other reactions. This reduction in their resistance leads to their greatly increased destruction in this condition. In the liver certain of their components are changed to bile products. This leads to a condition of hypercholia and its attendant symptoms. The increased amount of bile products acts upon the sympathetic system and reduces the vasomotor tone in all the abdominal and pelvic organs, causing characteristic symptoms thereby. In icterus graviditatis, therefore, the initial cause is the reduced resistance of the red blood cells. The manner in which the resistance is brought about is not as yet definitely known. Many ascribe it to malarial poisoning and others to syphilis. Most of the patients who develop this variety of icterus have been for years in a so-called anæmic condition and are constitutionally reduced in vitality. It is probable that in such many causes may contribute to reduce the resistance of the red blood cells.—*Monatsschrift für Geburtshilfe und Gynäkologie.*

Hepatic Contusion, Caused by Collision with a Street Car.—Anna M. Handshaw reports this case. The patient was a man over forty years of age, who had been blind since infancy. He was struck by the hand-rail of a cable car. The primary symptoms and signs of the lesion were shock and muscular contusion, also slight injury to the floating ribs, but no fracture. The patient suffered from bradycardia and the temperature dropped below normal. He was restless and his respirations were limited. The contusion caused pain and discomfort on the change of position in bed, or when pressure was applied to the right side. As the muscles gained their integrity, the abdominal character of the breathing was restored and the pain on deep inspiration ceased. There was a sensation of oppression over the heart and lungs. Symptoms of abscess or suppuration developed. Chill and collapse, followed by rise of temperature, indicated a septic condition. There was pain in the right shoulder, jaundice, cyanosis of lips and finger nails, perspiration, vasomotor paresis, and "a feeling of a board inside of the ribs." If there was abscess it was probably encapsulated and slowly absorbed with the resulting cachectic condition of the patient. The patient left his room for the first time over three months after the accident.—*The Woman's Medical Journal.*

The Treatment of Sciatica.—Vernon A. Chapman holds that if nerve-stretching (neurectasy) were more often chosen as the first rather than as the last resort, the other numerous remedies would not need to be so frequently employed. He gives full directions for the proper manipulations, according to the seat of the pain. The degree of force to be used must be determined by the existing conditions in each case, and must be regulated by the common sense of the operator. In severe cases the pain aroused by the manipulations is so severe that general anæsthesia must be employed for the first few treatments. In mild cases the patient himself can employ this method of nerve-stretching to a certain point· Let him stand with feet together and legs straight; then let him bend himself forward at the hips, keeping the legs straight, and touch the toes with the tips of the fingers of both hands simultaneously; or let him sit upon a firm flat surface, with legs extended before him; then, by bending forward, keeping the knees unbent, grasp a foot by each hand, and firmly flex it upon the leg. This procedure will be found quite difficult at first, but can easily be performed in a short time by perseverance, and if thus practised by the sciatica victim, will ward off many attacks of his enemy.—*The Canadian Journal of Medicine and Surgery.*

Immunity, Natural and Artificial.—Victor C. Vaughan holds that the most important factors in natural immunity to bacterial infection are the following: (1) Inability on the part of the microorganism to multiply in the animal body; (2) The destructive action of the phagocytes on the invading microorganism; (3) Plasmolysis, or the destruction of the invading cell on account of the composition of the new medium in which it finds itself placed. The agents employed in securing the condition of acquired immunity are as follows: (1) Treatment with attenuated cultures of the germ of the disease; (2) The employment of sterilized cultures of the specific microorganism, or the use of its toxins; (4) Treating the animal with cultures of the specific microorganism mixed with the other bacteria, or the employment of mixed cultures, in which the specific microorganism is present.—*Indiana Medical Journal.*

Case of Afebrile Pneumonia.—J. L. Winner reports the case of a man of forty-eight years, who came to the office suffering from dyspnœa. The respiratory movements were 48 to the minute, pulse 90. The left lung showed the physical signs of consolidation, yet there was absolutely no elevation of temperature. The patient would not stay in bed, but after the occurrence of rusty expectoration consented to stay in the house. On the fourteenth day of the disease no crisis was reached, but the patient gradually assumed the appearance of convalescence. On that day he left the house, went to visit the grave of his child, and when he returned home was attacked with hæmoptysis so profuse as to cause collapse, promptly followed by death. At no time had there been any rise of temperature.—*Virginia Medical Semi-Monthly.*

Clinical Department.

TWO CASES OF BRONCHIAL OBSTRUCTION IN PHTHISIS; TWO CASES OF RHEUMATIC CREAKING IN THE SHOULDER JOINT IN PHTHISIS; TWO CASES OF THROMBOSIS OF THE COMMON ILIAC VEIN AFTER TYPHOID FEVER; EMBOLISM OF THE BIFURCATION OF THE AORTA.*

By J. N. HALL, M.D.,
DENVER, COLORADO.

BRONCHIAL obstruction by enlarged bronchial glands in pulmonary tuberculosis, as I have heretofore stated, must be clinically much more frequent than it appears to be, judging from the rarity of such reports. The obstruction has been demonstrated so frequently post mortem that we have, I believe, abundant justification for a clinical diagnosis in such cases as the two here given:

CASE I.—A man, thirty-four years of age, came West with pulmonary tuberculosis, about six years ago. This has progressed slowly, with extensive dulness and moist râles in the left chest, and the right lung has recently been invaded. He has lost much ground in the last year. Tubercle bacilli are abundant. About three months ago he suffered so much from suddenly-increasing dyspnœa that he was compelled to stay at home. I found, in addition to the previous signs of chronic tuberculosis, a moderate increase in temperature, pulse, and respiration over the former condition, and severe suffering from shortness of breath upon even moderate exertion. Cyanosis was present under these circumstances.

The chest was retracted upon inspiration, and the left side lagged behind the right. Over the whole left lung, but more marked over the lower two-thirds, were diminished respiratory murmur and vocal fremitus, with marked inspiratory "crowing," or "cornage.' These signs persisted for about three weeks and gradually disappeared, without notable increase in expectoration. The general health of the patient has suffered markedly meanwhile, but the dyspnœa has decreased to its former amount. There were no signs of aneurism nor of intrathoracic tumor.

The best explanation that I can conceive of is that the enlargement of one or more bronchial glands encroached upon the primary bronchus, possibly interfering more with the branch to the lower lobe than with that to the upper, and that a subsidence by suppuration and emptying into the bronchus, or by decreased congestion, as mentioned in the report of the next case, restored the caliber of the tube. There is abundant pathological evidence to support such a supposition. Dr. Teele, with whom I saw the case, would venture no other explanation.

CASE II.—A man, twenty years of age, was admitted to the Arapahoe County Hospital, December 15, 1901. He had an old ankylosis of the right hip, stated by Dr. G. B. Packard to be the result of tuberculosis. There was a bad family history of consumption. At nine years of age, and at eleven and thirteen also, he had attacks of pneumonia. He has had some cough ever since the last attacks.

In July last he had acute rheumatism after exposure in a rain storm, and was in St. Anthony's Hospital for five months. He coughed all the time. Examination, on December 16, showed dulness in the right apex, more marked behind, with abundant moist râles upon both sides. Respiratory murmur and vocal fremitus were much decreased upon the right side. There was marked inspiratory dyspnœa, accompanied by indrawing of the chest walls, and lagging of the right side. Here was heard exceedingly harsh inspiration with fremitus, but vocal fremitus was decreased. The left pupil was slightly larger than the right. Examination of the heart gave negative results; the radial pulses were equal and synchronous; there were no tracheal or other signs of aneurysm. The temperature reached 102°, respiration 26; pulse, 80 to 90. The sputum showed tubercle bacilli with staphylococci and diplococci. Urine, 1026, with a trace of albumin, but no sediment of note.

From his great cyanosis and his history, miliary tuberculosis was suspected, and he was shown at the clinic at the hospital, and this possibility mentioned. Because of the chance that the unilateral bronchial obstruction was caused by the pressure of an enlarged bronchial gland, the patient was treated, like one with acutely enlarged scrofulous glands in the neck, with large doses of iodide of iron. In a few days the unilateral signs and the dyspnœa and cyanosis had disappeared, and in two weeks the patient insisted that he be discharged to return to work. He then had the signs of his chronic pulmonary tuberculosis, but all acute symptoms had disappeared.

In this case the rapid subsidence of the supposed gland enlargement, without increase of expectoration, leads me to think that the pressure was from increase in size owing to fluxion, and that this pressure was relieved by subsidence of the inflammation, and not from rupture of a suppurating tuberculous focus, as probably occurred in a case previously reported.*

To one familiar with the rapid increase in size of tuberculous cervical glands in children and young adults, and their frequently marvellous subsidence, without suppuration, under iodide of iron and cod-liver oil, the diagnosis offered in this case will certainly appeal very strongly.

The recent report of Blodgett, in the *Boston Medical and Surgical Journal*, upon auscultation as applied to diseased joints, leads me to report the following cases. In one of them I believe that a superficial examination may have led to an erroneous diagnosis of pulmonary tuberculosis, while in the other, the creaking was associated with this disease. If, as seems possible, it caused the error in diagnosis in the first case, it should be mentioned distinctly, that it may not cause further trouble.

CASE III.—A man, thirty-five years of age, physician, family history good. After severe professional work in an Eastern city, he fell off in weight from 147 pounds to 141 pounds, and then took cold by being thoroughly drenched in a July squall. Acute tonsillitis developed, followed by tracheitis and cough, with expectoration for a week, and a moderate temperature. No bacilli were found in the sputum. A few indefinite râles were said to have been found by two physicians in the left apex, and at the tenth rib behind upon the left. He had been sent here with the diagnosis of tuberculosis. When I saw him he had been in Colorado seven weeks, and weighed nine pounds more than ever before. Temperature and pulse were normal; there was no cough nor expectoration. Four physicians had examined him and found no signs of disease in his chest, and all were men of excellent standing in the profession. I found nothing within the chest, but the rheumatic creaking at the left shoulder led me to inquire further into his history.

He had had a mild rheumatism, which had for some months affected the left shoulder, causing occasional discomfort in its use. He had noticed the creaking, and the same sign had existed in two or three other joints. When the possibility of this creaking having erroneously given rise to the suspicion of intrathoracic trouble was suggested, he thought it quite possible in view of the negative finding of so many observers here in Colorado.

---

*Read before the Denver and Arapahoe County Medical Society.

**Philadelphia Medical Journal*, December 1, 1900.

Near the angle of the scapula was heard a mild creaking noise, which I at first supposed to be pleuritic. It increased in intensity until, over the scapulo-humeral joint it was loud and palpable to the touch. When the patient stood in such a way that the arm hung freely, it entirely ceased, recurring if the arms were folded across the chest again.

I have occasionally heard this sign before, as others certainly have, but did not appreciate that it might lead to error. In this case it offers an easy explanation of what I feel sure was an erroneous diagnosis, if we assume the early examinations to have been rather superficial ones. The possibility is at least worthy of consideration.

Case IV.—A man, thirty years of age, had marked dulness and fine râles over the left apex, with probably a small cavity. The latter was not located, but suspected, because of profuse hæmoptyses with blood almost free from air. After he had gained sixteen pounds in weight, and made a good start toward recovery, precisely the same condition, as above described, was one day found over the left scapula. The sign has not reappeared, and the patient is practically well, weighing now twenty-three pounds more than ever before.

I scarcely see how one familiar with auscultation could mistake such a sound for one proceeding from within the lung, but its resemblance to pleural friction is so great that one might easily be deceived if he did not follow up the sound to its source. With reasonable care no justification exists for error.

I have recently seen two cases in which thrombosis of the common iliac vein had apparently occurred years before, following typhoid fever. Collateral circulation, although fairly efficient, still failed to keep the affected leg free from œdema.

Case V.—F., thirty-seven years of age, a ranchman, was admitted to the Arapahoe County Hospital in December, 1901. He was shown at the clinic on account of a chronic biliary obstruction, due probably to either impacted gallstone or malignant disease. He refused to permit an exploratory incision. Some fifteen years before he had had typhoid fever, and with it venous thrombosis of the left leg. This leg had always remained slightly enlarged, and œdema of the foot was still occasionally found.

From the left groin two veins, each as large as a lead-pencil, ran transversely to the right side, carrying blood in that direction. Five or six veins, a little smaller, carried blood upward toward the navel. The rapid upward current could be easily demonstrated by stroking the veins downward.

The great size of the collateral vessels leads me to think that the venous path from the left leg to the vena cava inferior was entirely cut off by upward extension of the crural thrombosis. The pelvic venous circulation upon this side may well have been involved by thrombosis of the internal iliac vein, if we are to judge by the abundant collateral circulation. The occasional extension of venous thrombosis from one leg to the other by involvement of the inferior vena cava is well recognized. These cases are of especial interest at this time, for in the past few years a great number of patients with typhoid fever have suffered from milk leg—a number vastly exceeding the one or two per cent. usually given in text-books.

Case VI.—G., a man, twenty years of age, seen December 14, 1901, with Drs. Eisenstadt and Moleen, and reported by their kind permission. His chest condition and anæmia do not concern us here. Six years ago he had typhoid fever and right crural thrombosis. The right leg still swells after exertion or long standing. An immense superficial vein carries blood upward from the right groin to the edge of the liver dulness, where it disappears within the abdomen. The patient states that many others existed for one or two years after the fever. In this case the external iliac vein was certainly thrombosed, and probably the common iliac as well.

In a recent case seen at the Arapahoe County Hospital, in which an immense sarcoma of the mediastinum cut off the circulation through the superior vena cava, the anterior chest wall was marked with enormous veins, and many of them contained phleboliths. None were found in either of these cases, although sought for.

In both the cases reported, it is evident that small superficial abdominal veins carried the blood upward to some anastomosis with the inferior vena cava. The superficial circumflex iliac, superficial epigastric, deep circumflex, and deep epigastric, and the small pubic veins were all enlarged, and doubtless many deeper veins participated in the compensation.

Case VII.—*Embolism of the Bifurcation of the Aorta.*—S., a man, about thirty years of age, seen with Dr. W. E. Shotwell, to whom the entire credit of the diagnosis is due.

This man had suffered from valvular heart disease for years, and had come down to Denver from the high altitude of Cripple Creek, to recuperate. He intended to spend the day at one of our summer resorts, when he was suddenly awakened with terrible pain in the legs, as he lay dozing upon a sofa. I saw him about four hours later.

Dr. Shotwell and I found the condition as follows: The legs were blue and cold, the only pulsation to be obtained being a very slight and feeble one in the left femoral artery, with possibly a slighter one in the right; it ceased in both soon after. The heart was much enlarged with wavy impulse, and a loud apex systolic murmur was transmitted to the left. His dyspnœa and other symptoms had been characteristic of mitral regurgitation. The pulse was 120, very feeble, and the pain was still severe, although relieved somewhat by the hypodermic use of morphine, strychnine, digitalis, and whiskey, and the external applications of heat.

It was obvious that an instantaneous obstruction of the crural circulation had occurred at the time of his sudden pain. The known frequency of the development of the ball thrombus in the left auricle led us to believe that the trouble came from the passage of such a thrombus from the auricle to the ventricle, and thence to the bifurcation of the aorta. It must have been small enough to pass the valves, but too large to enter any artery, apparently, after reaching the aorta. Thrombosis soon completed the obstruction after the embolus lodged.

The patient died about thirty-six hours after the attack. No autopsy could be obtained. Both legs were black for some hours before the fatal result

The Italian Language at Congresses.—The government of Italy has instructed the diplomatic and consular agents in foreign countries that whenever invitations to attend international congresses are addressed to them they are to reply that Italy will abstain from taking official part in a congress in which the use of any language other than French is permitted, while Italian is excluded

CASE OF RATTLESNAKE BITE.

By WILLIAM A. WALKER, M.D.,
CAIRO, GA.

On March 7 a boy nineteen months old was bitten at 6 P.M. by a diamond-backed rattlesnake, two feet eight inches in length. The fangs entered just above the inner maleolus of the left leg. The parents of the child, attracted by its screams, almost immediately stopped the circulation in the leg by tying the mother's apron string above the bite. This was reenforced by a second constriction just above the knee. When I saw the patient about one hour later there were no symptoms of absorption of the venom, as the child's condition was good with the exception of interference with the circulation in the constricted leg. Six longitudinal incisions were made through the skin and deep fascia and partly into the muscles, over the region of the bite, to which were added two crucial cuts. The mother was then requested to make labial suction, which she did very thoroughly, bringing out a considerable quantity of blood, which had a distinctly greenish tinge. Two drachms of solution of permanganate of potassium (10 grains to the ounce) were injected into the tissues around the location of the bite, as directed in Wyeth's Surgery. The cords were loosened for about a minute and then re-applied. This operation was repeated several times, in order to prevent any overwhelming influx of venom into the circulation. As this was being done the child became very pale and nauseated, and to counteract this condition about a drachm of whiskey was given by hypodermic injection. In thirty minutes these alarming symptoms disappeared. The constriction, which was not tight enough to interfere with the supply of blood to the limb, but prevented a rapid return of the venous current, was not entirely removed for twenty hours. The wound healed entirely in two weeks. There was only a slight sloughing in the center of the crucial incisions.

I am of the opinion that this child's life was saved by the prompt constriction of the leg above the wound, the thorough labial suction, and the neutralization of the venom by the permanganate of potassium.

A CASE OF TYPHOID FEVER FOLLOWED BY PARALYSIS OF THE PHARYNX AND PROBABLY OF THE ŒSOPHAGUS.

By ISIDOR GINZBURG, M.D.,
NEW YORK.

J. O., female, eleven years old, became sick March 28, 1902. The initial symptoms were severe headache, general lassitude, and some fever. For five or six days in succession the patient was fed on different "headache powders," in the supply of which our drug stores are so rich and our druggists so liberal. At last the parents decided to send for a physician, and I was called to see the patient. After a thorough examination, I made a diagnosis of typhoid fever of a meningeal type. I advised the parents to send their child to a hospital, which they refused to do

Being unable to give the cold-bath treatment, which is simply impossible in a private house without the help of competent nurses, I ordered cold sponging and the cold pack. On the third day after I saw the patient first a typical typhoid eruption appeared.

The fastigium was of rather short duration, lasting only about six days, There was no hyperpyrexia, the highest temperature reaching 104° F., but the morning remissions were slight. The condition of the heart was good, there were no pulmonary complications, and the intestinal symptoms were of a mild character. It was the condition of the nervous system that caused me uneasiness; the patient was nearly all the time in a state of low, muttering delirium, and, in spite of the cold packs and cold spongings and other therapeutic measures, there was no marked amelioration of the symptoms.

On April 11 the defervescence set in. The temperature began to decline, the condition of the pulse improved, and even the nervous symptoms became milder, though not to the same degree. While my prognosis up to this time was guarded, I became rather sanguine in sight of the improvement, and gave the best hopes for a rapid recovery.

The next day I was there with a medical friend, to whom I wanted to show the case. Both of us examined the patient, and we found everything in the best possible condition. At that time the rectal temperature was 100° F., and the pulse was of a good quality, 105 to the minute.

On the next morning, April 13, when I came to see the patient, I was informed by the father that she had been unable to swallow, since two o'clock; had taken no food or medicine for about ten hours. The temperature at that time was normal, pulse 110, respiration 30. As I could not find any lesion in the throat which would explain the symptoms, I came to the conclusion that it was a case of paralysis of the pharynx. A specialist, for whom I sent later, could find nothing except some erythema of the pharynx and larynx. The pharynx did not respond to stimuli, and, as a result, large amounts of mucus and saliva accumulated there, which had to be removed with pieces of cotton dipped in an antiseptic solution.

The whole interest in the case lies in that peculiar complication—the paralysis of the pharynx—which came on so unexpectedly. So far as I know no textbook mentions it.

A CASE OF QUININE POISONING.

By DANIEL DAVIS ROSENBERG,
STUDENT IN THE COLLEGE OF PHYSICIANS AND SURGEONS,
NEW YORK CITY.

Being troubled with malaria and being advised by my physician to take quinine, I took 24 grs. of quinine sulphate per mouth at about 9 o'clock on the morning of April 5.

At about 11 o'clock of the same morning there began an awful buzzing in my ears, which was soon followed by almost complete deafness. I became very dizzy, and a cold sweat covered the entire surface of my body. My appetite became almost ferocious, but to my chagrin I found that I could not chew any food on account of the pain such action caused my masseter muscles, and moreover I found my swallowing apparatus almost completely paralyzed, so that I was only able, with the greatest difficulty, to take a rather small quantity of milk by means of a glass tube. My pulse rate was at this time about 110, full and bounding, while my temperature was approximately 94.6°. I was, moreover, in a state of great depression.

At about 12 o'clock I lay down and fell into a heavy sleep and did not awake until 4 o'clock, when I felt perfectly normal again.

Since that time I have taken as many as 12 grains of quinine without the slightest effects, not even a buzzing in my ears.

Society Reports.

AMERICAN NEUROLOGICAL ASSOCIATION.

Twenty-eighth Annual Meeting, Held at the New York Academy of Medicine, June 5, 6, and 7, 1902.

First Day—Thursday, June 5.

Dr. Joseph Collins of New York, President, in the Chair.

Study of the Myospasms, Myokymia, Myoclonus Multiplex, Myotonia Acquisita, and Intention Spasm.—This was the title of a paper by Dr. George L. Walton of Boston. In his opinion the present classification of the spasmodic disorders is not uniform. Myoclonia, for example, is used both as a synonym for myoclonus multiplex and as a collective term including the fibrillary chorea of Morvan, electric chorea, etc. Persistent muscular quivering should not be named myoclonus multiplex. Myoclonus multiplex is symmetrical, involves large muscles, and represents a disorder of the central nervous system. General muscular quivering (best named myokymia) represents a purely muscular disorder, perhaps a faulty connection between the nerve terminals and the muscle fiber. The quivering does not necessarily indicate increased irritability, but may represent irregular lapse from tonicity through such faulty connection. Two cases were presented showing persistent general muscular quivering without atrophy, persisting three and five years respectively, and two typical cases of myoclonus multiplex were reported to illustrate the distinctive characters of these disorders. Under the tonic myospasms, a case of "intention spasm" was reported in which tonic spasm of the lower extremities appeared on every attempt to walk, and persisted. Neither the myotonic reaction nor the myotonic muscular disorder were present.

The following conclusions were drawn: (1) The term *myoclonia* as a collective designation for the unrelated disorders should be discontinued; (2) The term *myokymia* should be limited to cases showing, without hereditary or congential history, widespread muscular quivering, without atrophy or other indication of progressive degeneration of the nervous system, without constitutional symptoms, and without signs of present infectious or other acute disease. Cases should not be excluded, however, on account of preceding or introductory symptoms pointing to disease of the lower neurons, if such disease has either disappeared or come to a standstill; (3) The term *myoclonus fibrillaris multiplex* should not be applied to such cases, since it suggests a relationship between myokymia and the paramyoclonus multiplex of Friedreich, with which it has nothing in common; (4) *Paramyoclonus multiplex* should be used to designate bilateral clonic spasms involving whole muscles or groups of muscles, generally those attached partly or entirely to the trunk; (5) The term *myotonia acquisita* should be limited to non-hereditary and non-congenital cases in which otherwise healthy individuals present the typical motor disorder, or the typical reactions of Thomsen's disease. This term should not include the rigidity accompanying marked intestinal disorder or pronounced psycopathic states, even though the rigidity in the latter conditions may be increased by voluntary movement; (6) The tendency to spasm on attempted voluntary movement, unless accompanied by the typical motor disorder, or the typical reactions of Thomsen's disease, should be classed as intention spasm.

Paramyoclonus Multiplex.—This was the report of a case by Dr. F. W. Langdon of Cincinnati. The patient was a girl thirteen years of age. The onset of the attack was attributed by her mother to fright by her brother who was in the habit of teasing her. There were violent shock-like contractions of the muscles of the trunk and of those attaching the limbs to the trunk. They rarely descended below the knees or elbows. The frequency with which they occurred was from thirty to eighty shocks per minute. The face, hands, and feet were not involved. The wrists, fingers, ankles, and toes were flaccid even during the muscular contractions of other parts. The spasms were symmetrical, but with a tendency to greater activity on the left side. The contractions ceased during sleep, but had not ceased for a half hour consecutively during waking hours for six weeks. The patient was still under observation. Treatment so far by anti-spasmodics had merely modified the violence of the contractions.

Dr. N. E. Brill of New York presented a case of paramyoclonus multiplex, and exhibited the patient, a girl of sixteen, whose disease started one year ago. She was treated during this time by Dr. B. Sachs at the Polyclinic and discharged therefrom as cured. Later, she entered the hospital with all the old symptoms intensified. The disease began after a severe fright, the clonic spasms involving almost all the muscles of the upper and lower extremities, including the flexors and extensors of the hands. There were no movements below the knees. The sternomastoids on both sides and the abdominal muscles were involved. Shortly after she came under Dr. Brill's observation the speech muscles became affected so that she articulated with difficulty, her articulation being snappy and explosive in character. There were at no time fibrillary twitchings in the muscles. She never had rheumatism or chorea. The distribution of the muscular spasm was more extensive and involved more muscle groups than any case under the speaker's observation or reading. He indicated the possible relation in this case to hysteria, because, while drugs had no influence on the disease, improvement was brought about by suggestion. The patient, however, showed none of the sensory stigmata of hysteria. He also mentioned the difficulty of distinguishing between this class of cases and generalized tic convulsif. of the French writers.

Dr. M. Allen Starr of New York referred to a similar condition as occurring in a patient under his observation. A young man, thirty-one years of age, had suffered from the same affection about eight months. During an attack of the grippe he was frightened and this mental shock was the active cause of his trouble. His spasms were identical with those we expect to find in paramyoclonus limited to the trunk muscles. The patient also had the same condition of the voice and speech as noted in Dr. Brill's patient. The voice was extremely irregular and he gave vent to peculiar involuntary sounds. During a four months' stay in the hospital, nothing produced any benefit except rest in bed, in a quiet room, with massage and baths. Under this treatment he improved so much that one month ago he went home and now has a spasm only occasionally, once in two or three days, each lasting but a few minutes.

Dr. Morton Prince of Boston mentioned a case in which the spasms were confined to the legs and developed as a traumatic neurosis following a carriage drive, the carriage being overturned by a trolley car. The same night there developed marked spasms of the lower extremities, confined almost entirely to the quadratus femoris on each side, but also extending over the posterior group of muscles when an attempt was made to move them. These spasms persisted for many years. The nerves were submitted to the operation of stretching, the legs being bent backward and upward toward the shoulder as far as possible. Immediately following this, there was a change in the character of the spasms and they continued during the night, but the next morning they disappeared and have been absent ever since. It was of interest to note that this began as a traumatic neurosis and ceased abruptly. It is doubtful whether any real injury was done to the nerves themselves.

Dr. B. Sachs of New York had seen the patient shown by Dr. Brill, and said that the sudden cessation of the movements under the simple rest treatment and also the equally sudden return of the phenomena under emotional excitement, were quite noticeable.

Dr. J. W. PUTNAM of Buffalo had observed a patient in whom the voice was of a peculiar character. He thought it was often impossible to differentiate between what is called hysteria and the spasmodic neuroses under discussion. We did not know just what the nature of hysteria was, but adapting the usual conception of it, hysteria might imitate other diseases in which there was shown a tendency of the nervous system to break down. There was certainly a sliding scale between the two, and we should not attempt to make a very sharp distinction between them.

Dr. CHARLES K. MILLS of Philadelphia called attention to the occurrence of a form of tonic myospasm or myotonia, closely simulating Thomsen's phenomena, in a case of brain tumor not situated in the motor region. In a patient now under his care, he had witnessed a gradual development of this condition in association with other symptoms of organic brain disease. There were no motor or sensory disturbances, but there had been an increasing disturbance of the mental powers, such as judgment, memory, etc. Several years ago, he had seen another case in which Thomsen's disease was closely simulated. A brain tumor was found to be the cause of the symptoms.

Dr. SMITH BAKER of Utica believed it was entirely useless to attempt to help these cases with any ordinary therapeutic measures. He had never been able to benefit them with medicines. He thought that more attention should be paid to the mental condition than to the spasm. Let them alone, isolate them, and study how to perform some deep phsychical impression. This would go as far as anything he was aware of in producing good results.

Dr. F. X. DERCUM of Philadelphia was much impressed with the psychical element in these cases, and also with the close relation which they seem to bear to hysteria. He had been in the habit of regarding them, especially when there has been a history of any psychical origin, as of an hysterical nature. Incurability was therefore not in keeping with this view. These cases bore some relation to general convulsive tic, which is an hereditary neuropathy. The muscular tracts were undoubtedly influenced by potassium, calcium, and sodium salts, and here, perhaps, was where chemistry might be of service.

Dr. WALTON said that the absence of fibrillary twitching in the cases reported showed that this symptom was not a common one in myoclonus multiplex. While Dr. Baker's observation as to the mental factors were quite accurate as regards myoclonus multiplex, they did not apply to myokymia, or to myotonia congenital or acquired.

Dr. Langdon concluded that close lines could not be drawn as to the cause. There were no commonly recognized stigmata as in hysteria. If the cases were largely psychic, how was one going to reverse the psychic processes? So far as a cure was concerned, ordinary remedies did not seem to have much effect.

Disseminated Sclerosis Causing Ocular Palsies and Spasticity with Loss of Knee-jerks.—Dr. WILLIAM G. SPILLER of Philadelphia read a paper with this title. The necropsy showed the existence of numerous sclerotic areas throughout the brain and spinal cord. In 1891 the patient, a woman, forty-one years of age, complained of numbness in the feet, and soon the legs became numb. She had at this time progressive loss of power in the lower limbs and staggering gait. Within two days the numbness extended as high as the waist, and she complained of girdle sensation, and had complete paralysis of the lower limbs. She had also incontinence of urine and fæces. The disturbance of gait soon disappeared, and she was able to walk until 1899, but staggered. She complained of shooting pains at times in the knees, extending to the ankles. In 1901 her speech was somewhat drawling. The lower limbes were completely paralyzed, were much wasted and spastic, slight irritation causing the limbs to be drawn up involuntarily, and yet the patellar and Achilles reflexes were absent. The knees and feet were inverted The Babinski reflex was pronounced. Sensation was normal everywhere. Voluntary movement in the upper limbs was impaired, and the grasp of the hands was very feeble. The hands were very much atrophied. Reflexes of the upper limbs were normal. Mentality was feeble. She had almost complete external ophthalmoplegia and partial atrophic cupping of each optic disc Iritic response was good. The interesting features of this case were: the pronounced muscular atrophy, the secondary degeneration of the pyramidal tracts in a case of disseminated sclerosis, the loss of the patellar and Achilles reflexes with great spasticity of the lower limbs—the loss of these reflexes probably being the result of sclerotic areas in the posterior columns of the lumbar and sacral regions, and the almost complete external ophthalmoplegia resulting from sclerosis of an area in the nuclei of the third and fourth nerves.

Dr. KNAPP related the history of a patient in whom there had been gradually increasing headache and vertigo for several weeks, the general symptomatology being somewhat similar to that in the case reported by Dr. Spiller. This was followed by an apathetic mental condition, slowness in speech, post-neuritic optic atrophy, unequal but active pupils, uncertain gait, exaggerated knee-jerks and ankle-clonus, increased muscular rigidity, and general diminution of sensibility to pain and touch. The mental dulness and apathy increased, and the diagnosis rested between a tumor of the cerebellum and one of the frontal lobe. Death soon followed. The autopsy revealed a cerebellar tumor and basal meningitis.

Dr. WALTON had lately seen a patient with marked bilateral contracture associated with hemiplegia of comparatively recent occurrence. He thought that in the absence of the knee-jerk in spastic paralysis we should take great care to exclude variations of tonicity from the normal before having recourse to an additional focus of disease in the reflex arc. He had seen absence of knee-jerk and of cutaneous reflexes in cases of tumor with spastic paralysis, and also the cutaneous reflexes lost during the rigid stage of meningitis to gradually return during relaxation.

Dr. STARR had observed a child who presented the typical symptoms of multiple sclerosis developing at the age of seven years after an attack of measles. There was the characteristic spasmodic condition of the lower extremities with exaggerated reflexes and evidence of descending degeneration in both pyramidal tracts. The only question that arose in his mind was whether the descending degeneration was secondary to the sclerosis. He was glad that Dr. Spiller had presented pathological observations which makes it evident that multiple sclerosis may have a secondary descending degeneration.

Dr. J. W. PUTNAM said that as disseminated sclerosis is not very common in this country, he wished to state that several years ago he had seen a case in which very extensive degenerative changes were found in the cord. This patient also had marked disturbance in the action of the eye muscles.

Dr. SINKLER thought that the symptoms as described in the case of Dr. Spiller were more those of a diffuse myelitis than a disseminated sclerosis.

Dr. D. J. McCARTHY of Philadelphia asked Dr. Spiller to explain the loss of reflexes in cases of patches of sclerosis.

Dr. Spiller, in closing the discussion, said that it was extremely difficult to decide whether or not the knee-jerk was lost in cases of rigidity of the limbs. With regard to infants we should be guarded in our statements as to these reflexes. He had seen loss of knee-jerk in disseminated sclerosis a number of times and had attributed it to sclerotic patches. Generally, one did not find, as in this case, permanent bilateral contraction in unilateral lesions. Descending degeneration in multiple sclerosis did exist, but it was very rare.

Traumatic Myelitis Causing Symptoms of Central Hæmatomyelia.—Dr. SPILLER read a paper with this title, and reported a case because of the dissociation of sensation of the syringomyelic type following a fall without fracture of the vertebræ. It has been assumed that under such conditions this symptom-complex indicates hematomyelia. The case showed that traumatic myelitis, with very insignificant hemorrhage, could produce the same dissociation of sensation as hematomyelia. The recovery of motor power in the lower limbs had been very great, although intense degeneration of the pyramidal tracts was shown by the Marchi method. The case showed that much motor power might exist even when the degeneration of these tracts was considerable. The nerve-cell bodies of the anterior horns of the cervical swelling, especially at the eighth servical segment, were much degenerated, and this explained the greater intensity of the paralysis in the hands and fingers, even though the mild traumatic myelitis was above the sixth cervical segment. The case also showed that degeneration of nerve fibers and cell-bodies from trauma might occur within the spinal cord without fracture of the vertebræ, and might resemble that produced experimentally. This fact had much medicolegal importance.

Combined Tabes and Multiple Sclerosis.—Dr. Wharton Sinkler of Philadelphia read a paper with this title. He described a case in which pronounced symptoms of multiple sclerosis were combined with those of locomotor ataxia, and remarked upon the fact that, while multiple sclerosis gave rise to a diversity of symptoms according to the location of the diseased areas, he had never known of a case in which the symptoms of this disease were so conspicuously blended with those of tabes as in the following case: The patient was a man sixty-two years of age. He had had syphilis as a youth, but never had any secondary symptoms. For many years he had noticed a tendency to shaking of the hands in doing delicate work, but for the past eight years there has been marked tremor on voluntary effort. About eight years ago he began to have attacks of intense lightning pains in the legs. The pain was usually concentrated in a small area, the spot being not much larger than a ten-cent piece. For about the same length of time the legs have felt dead and numb. About the same time he suddenly found that there was loss of vesical control; that is, at night he would have sudden and unconscious emptying of the bladder. This condition has persisted so that he has been obliged to wear a urinal. The patient's gait was not characteristic of locomotor ataxia, but was unsteady. He walked long distances habitually and did not experience any sense of fatigue. The station was bad, that is, there was considerable shaking of the body from tremor of the legs. Standing with the eyes closed, there was great swaying, and he would fall if not supported. The knee-jerk and Achilles jerk were absent. Plantar reflex was present, but easily exhausted. No Babinski sign. There was extreme intention tremor in both hands, more marked in the right. It was impossible for the patient to carry a glass of water to the mouth with the right hand, although by some dexterity he succeeded in accomplishing this with the left. He was unable to write. An attempt to write his name resulted in an illegible scrawl. The Argyle-Robertson phenomenon was absent, and there was no change in the fundus of the eyes. The speech was not scanning.

Course of the Sensory Fibers in the Cord, and Some Points in Spinal Localization.—This was the title of a paper and the report of a case by Dr. Morton Prince of Boston. The case was of value in that it showed the existence of a pathway for sensory fibers other than in the posterior columns. The patient had been stabbed in the neck. The knife entered between the fifth and sixth cervical vertebræ and severed approximately the posterior half of the cord, the section being carried farther forward in the left half of the cord than in the right, so that both posterior columns were cut clean through, and the lateral columns on the right as far forward as the anterior boundary of the pyramidal tract, but on the left it extended ventrally so as to include a portion of the anterolateral field. During life tactile sensation was preserved on the left half of the body, but abolished on the right half as high as the set of the lesion. As the posterior columns were completely severed, tactile impressions from the left half of the body must have ascended in the anterolateral field. It was evident also that they must have crossed to the opposite half of the cord, otherwise there was no way of explaining the anæsthesia on the same side of the body as that on which the section of the cord was of the least extent. It would also appear that this path for tactile impressions, after crossing in the cervical region, must ascend somewhere in an area represented by a triangle, the posterior leg of which corresponds to the line of incision on the right side, and the anterior leg to the line of incision on the left side of the cord. The case also corroborated our knowledge of spinal localization, although the paralysis resulting from the lesion varied somewhat from the usually accepted view. There was absolute paralysis of the extensors of the forearm with preservation of the function of the flexor group, showing that the centers for the triceps do not extend above the seventh segment. The distribution of the sensory loss also presented some points of interest. The report of the case was a preliminary one, as the microscopic examination of the cord was not yet complete.

Dr. Mills said that aside from the motor conditions present, it would have been of great value to determine the muscular sense, and the pain, temperature and tactile senses.

Dr. William G. Spiller of Philadelphia thought that Dr. Prince's case seemed to show that the tactile fibers were not confined to the posterior columns. He believed in the study of the pain and temperature senses, and felt quite sure that had a microscopic examination been made, the lesion would have been found to extend further anteriorly.

Dr. Prince admitted that the tactile sense only was investigated in this patient, the pain and temperature senses being disregarded. The question at issue was that of operation. He was concerned solely with the idea of looking for the height of the lesion in the cord.

Exophthalmic Goiter after Thyroidectomy.—Dr. J. Arthur Booth of New York read a paper with this title and reported the results in eight cases of Graves' disease after partial thyroidectomy. All were in women from seventeen to forty-two years of age. Exophthalmos, goiter, tachycardia, and tremor were present in every case. One patient died twenty-four hours after the operation, but the seven others had been under observation since the operation for periods ranging from two to nine years. Three were cured and four were practically well, all of the prominent symptoms having more or less subsided, the pulse being from 80 to 84. The following conclusions were drawn: (1) Cases of Graves' disease are cured both by thyroidectomy and by resection of the sympathetic; (2) Sudden death may occur during or after the operation, which is due to an already weakened heart, faulty technique of the operator, or nephritis; (3) in the majority of cases the thyroid gland dominates the disease.

Dr. Starr believed in the importance of operation in such cases. He had recently seen a patient in whom the gland was enlarged downward and backward, and so did not produce so much protrusion as usual. The operation resulted favorably and the patient was in fairly good condition. He believed that the activity of the gland was responsible for the disease.

Dr. Dana said that the statistics regarding this operation, and especially that of the removal of the sympathetic, were very misleading. There was no evidence that removal of the sympathetic ganglion would cure Graves' disease. If one were to select a series of seven cases treated medically and go back six or seven years, he could report as good results as Dr. Booth had. It was most important to bear in mind that these patients could be improved more promptly by operation, provided it did not kill them. He thought the disease was essentially or primarily a psychosis, with some disturbances of the nerve-centers and increased glandular activity. He had collected about twelve cases of Graves' disease in which death had occurred within three or four months, and nearly all had bulbar symptoms, facial palsy, etc.

Dr. Hirsch said that as a rule surgeons do not publish the unsuccessful or fatal cases.

Dr. William Osler of Baltimore had personal knowledge of two patients dying during the operation, and he had heard of a third case. If there was any clinic from which reliable figures were to be had, it was Kocher's clinic in Berne. Kocher concluded that in the surgical treatment of the disease we had by far the best means at hand for curing a large percentage of cases. Osler thought that little was known as yet of the good that might be obtained in Graves' disease from surgery.

Dr. B. Sachs said we should be more conservative in regard to surgical intervention, for many cases will get well by simple means. Exophthalmic goiter was not such an unfavorable disease as it was generally supposed to be. He mentioned a patient who had been successfully operated upon eight years ago. In this case there was tremendous exophthalmos. Both the tachycardia and the exophthalmos diminished, and there was improvement in the general health.

Adiposis Dolorosa.—Drs. F. X. Dercum and D. J. McCarthy of Philadelphia reported the results of an autopsy in a case of adiposis dolorosa.

Dr. Spiller had made sections in the case reported, but did not find any affection of the hæmolymph glands.

Amaurotic Family Idiocy.—Dr. B. Sachs of New York reported a case with the result of the autopsy, which showed degeneration in the gray matter throughout the entire central nervous system.

Asthenic Bulbar Paralysis.—Dr. William M. Leszynsky of New York presented two patients with this rare affection. The first patient was a girl twenty years of age. She had been subject to frequent attacks of right-sided migraine without vomiting, but with transient obscuration of vision since her fourteenth year. Otherwise, she was perfectly well until about a year ago, when she first noticed slight difficulty in speech while reading aloud, her voice becoming of a nasal quality. This gradually got worse, and a month later there was transient diplopia, and in attempts at swallowing, food would regurgitate through the nose. Six months ago the eyes did not close completely, and three months later there was occasional weakness with heaviness in the right arm and hand, and subsequently the left arm and band became similarly affected. In the last six months, there had been dysphagia and difficulty in mastication. She was now easily exhausted after talking or chewing for a short time. She therefore took very little nourishment and was losing weight. There were present incomplete bilateral lagophthalmos and facial paresis, paralysis of the palate, and paretic masseter muscles. The reflexes were easily exhausted. The second patient was a married woman twenty-two years of age. From time to time during the year, before coming under observation, she had suffered from attacks of dysphagia, in which fluid food regurgitated through the nose. Several times there had been transient paresis of the left arm and leg. Later she complained of headache, gastric pain, nausea, and vertigo lasting three days. There was some fever but no vomiting. This was soon followed by vertigo, diplopia and ptosis of the left eye, from which she gradually recovered. During the next eight months she had several attacks of vertigo, diplopia, and ptosis alternating between the two eyes, from all of which she recovered spontaneously in a few days or a few weeks. At present there were partial ptosis of the left eye, bilateral facial paresis, nasal quality of the voice, difficulty in mastication, due to rapid exhaustion of the masseters, paresis of the palate, dysphagia, and regurgitation of food through the nose. After talking a short time she was unable to continue on account of rapid fatigue. On awaking, all of these symptoms subsided more or less, but began again in a few hours and increased during the day.

The Posterolateral Scleroses.—Drs. C. W. Burr and D. J. McCarthy read a report of nine cases of diffuse sclerosis affecting the posterior and lateral columns of the cord, and presented a classification of combined diseases of the spinal cord.

Dr. J. J. Putnam said that the variety of toxic conditions which gave rise to this affection was considerable.

Dr. Walton thought that sufficient stress had not been laid on the ischæmic form due to arteriofibrosis. The parts of the cord usually attacked were those physiologically supplied with the least blood, and it was reasonable to suppose that they might first succumb in the presence of even moderate arterial changes.

Dr. Spiller said that the disease is almost invariably a diffuse process when it is due to anæmia.

Transverse Lesion of the Midthoracic Segments of the Spinal Cord.—Dr. Adolf Meyer of New York reported a case of probably syphilitic myelitis of the fourth thoracic segment destroying the entire cross-section with the exception of the greater part of the posterior columns (the most ventral part and the commissure were destroyed), a few pyramidal fibers, and the head of the dorsal horns. The symptoms were for one year before death: analgesia and thermanæsthesia below the sixth rib on the right, and the fifth rib on the left side; a zone of slight thermanæsthesia over the fourth rib, paralysis below the thorax (slight movement of the thigh and of the right toes occasionally possible); involuntary pulling up of the thighs, at times accompanied by shoot-pains. There was no disorder of tactile sensibility, pressure sense, tickle sense, or sense of position.

Dr. Prince said that our anatomical knowledge as to the course of the fibers is far in excess of our physiological knowledge. We must admit that there are at least two tracts going up carrying tactile and pain impressions.

Second Day—Friday, June 6.

Paralysis of All Four Limbs and One Side of the Face, with Dissociation of Sensation Developing in a Few Hours and Resulting from Meningomyeloencephalitis.—This was the report of a case by Drs. Charles K. Mills and William G. Spiller of Philadelphia.

Dr. Walton thought that such cases added materially to our knowledge of the reflex arc. The case confirmed the theory that any sudden cutting off of the upper portion of the cord produces a persistent loss of the knee-jerk.

Dr. Mills said that in spite of the enormous obliteration of the spinal cord, tactile sense was present over the entire body, with a complete loss of temperature and pain senses in the parts indicated.

Multiple Neurofibromatosis.—This was the title of a paper by Drs. Joseph Fraenkel and J. R. Hunt of New York. They dwelt upon the comparative rarity of the condition, stating that neurofibromatosis presents itself clinically under five different forms, as follows: (1) Tubercula dolorosa (painful tubercles) Wood; (2) Multiple neuromata of the skin (molluscum fibrosum—Recklinghausen's disease); (3) Neuromata or neurofibromata of a single peripheral nerve; (4) Neuroma plexiforme, pachydermatocele, and neuromatous elephantiasis; (5) Generalized neurofibromatosis, neurofibromata of the skin, cerebrospinal, and sympathetic nerves. Anatomically the disease is characterized by a fibrous hyperplasia, particularly endoneurial and perineurial, very rarely epineurial. This fibrous tissue is very succulent and shows no tendency to contract. This is.

perhaps, one of the reasons why most of the neurofibromata are without symptoms. Five cases were reported: A woman of thirty-one who had been sick for ten years and presented a clinical picture of transverse myelitis, in whom the autopsy revealed a large number of fibroneuromata and an isolated large neurofibroma within the vertebral canal. A young girl of eighteen, afflicted with neuralgia and paralysis of one lower extremity, in whom the operative removal of fibromata of the peroneal nerve led to recovery. The other cases were examples of Recklinghausen's disease and of peripheral neuromata without symptoms.

Dr. Dercum believed that a very broad distinction should be made between neurofibromatosis and adiposis dolorosa. In the latter condition there may be an increase of fat, which may be diffused, localized, or nodular, together with pain. Typical cases present fatty deposits, pain, and always some intense mental impression. In some cases there are hysterical manifestations; in others, a great tendency to hemorrhages into mucous membranes, epistaxis, hemorrhages into the retina, etc.

Dr. D. J. McCarthy said there were several types of adiposis dolorosa. One, in which the nodules appear to be more or less of a normal type but sensitive to pressure; another, in which the nodules are not sensitive to pressure; and a gouty type. He mentioned the case of a very fat woman who had attacks of acute tumor formations of fat; with each recurring attack there was a slight rise in temperature and more or less pain. A week after the subsidence of the attack there was no trace of the disease.

Dr. Fraenkel had seen a patient with general adiposis who lost sixteen pounds during the development of tuberculosis. It had been noted that this condition was more likely to develop in alcoholic subjects. The pathological examination of the fatty condition showed dilated lymph channels and enlarged lymph glands.

Pseudomuscular Atrophy.—Dr. G. M. Hammond of New York exhibited a boy nine years of age, who had been ailing for three years. There was at first a stage of muscular hypertrophy, but now the atrophic stage had developed. When first seen there was a condition of almost extreme helplessness, and the patient's general health was very poor. He was given three grains of thyroid extract three times a day, and he began to improve. He had gained five pounds in weight, his general condition was much better, and he was now able to walk upstairs. The speaker considered the condition one of dystrophy, the result of glandular deficiency and degeneration of the muscles.

Sarcoma of the Third Cervical Segment of the Spinal Cord. Operation. Recovery.—This was the report of a case by Drs. James W. Putnam and William C. Krauss of Buffalo. The patient was a man forty-five years of age. He had always been in good health and gave no history of injury. Two years ago he had attacks of sharp pain in the back of the neck radiating to the occiput. These increased in frequency, and were at times accompanied by vertigo. Later, numbness and weakness developed in both hands and arms. Then the legs became similarly affected until he was unable to walk. Motion was entirely lost in the muscles of the left arm and leg. There was some power in all of the muscles of the right arm and right leg, and no muscular rigidity. All of the reflexes were highly exaggerated with the presence of patellar and ankle clonus and the Babinski reflex. There was loss of control over the bladder and rectum, with total loss of sensation on both sides from the clavicle down. The vision was good and the pupils reacted readily to light. The diagnosis was made of tumor of the cervical portion of the cord and operation was advised. This was done by Dr. Roswell Park, April 28, 1902, and a sarcoma, involving the third cervical segment, was found and removed. During the five weeks since the operation there had been some improvement, which still continued. The writers claimed this case to be unique for the following reasons: (1) It was the only tumor of the spinal cord affecting the upper cervical regions which had been so far recorded; (2) It was the only cervical cord tumor which had gone on an uninterrupted course toward recovery; (3) It was definitely located and quickly removed without sacrifice of spinous processes and laminæ and the short incision closed with remarkable rapidity; (4) From the surgeon's standpoint it was located in the most inaccessible portion of the spinal cord by virtue of the cervical curvature of the spinal column offering a concave field for operation instead of a convex field; (5) It was the only tumor of the cervical segment of the cord in which distinct phrenic nerve disturbances were noted.

Dr. J. H. Lloyd of Philadelphia said that tumors of the spinal cord are rare, and therefore operations for their relief must be correspondingly rare. The subject of operation upon spinal tumors was a matter of recent development. He had had two cases that were operated on for spinal tumor. The case reported was an unusually successful one when it was considered that the operation was done in a dangerous region of the cord.

Dr. Walton said that his experience in a continuous series of cases, properly located, showed that the operation had not been attended with very good results. The readers of the paper had shown that the posture of the patient during the operation embarrassed the respiration. It seemed to him that in some of these cases of embarrassed respiration that it must be laid to another cause, which is most likely pressure upon the phrenic nerve.

Dr. Fraenkel referred to a tumor which was supposed to be situated at a certain portion of the spinal cord. The tumor was not found at the time of the operation, because it was performed one-quarter of an inch below the tumor. The patient died two days later, and the tumor was found near the entrance of the foramen magnum. He thought that caudal tumors were more important than tumors situated in other parts of the cord because we can offer a better prognosis.

Dr. J. J. Putnam of Boston mentioned three cases that had been operated upon in the Massachusetts General Hospital. In one case the tumor proved to be a sarcoma surrounding the dura like a collar at the junction of the cervical and dorsal cord. This patient was very stout and had embarrassed breathing during the operation. He died. Another case proved to be a cancer in the lower dorsal region. This also surrounded the dura like a collar, growing anteriorly. This patient suffered much pain. The nerve roots were severed and the pain was lessened. In the third patient the symptoms of tumor were perfectly characteristic, yet the tumor was not found. The nerve roots were severed, from which much relief followed.

Dr. J. W. Putnam, in closing, said that when the tumor was removed from the cord it showed that compression had been exerted upon the cord by a cup-like depression which was on both sides of the median line. The delay before operation was due to the obstinancy of the family physician, who insisted that there was no tumor present, but that it was a case of hysteria. The patient was going on to incomplete recovery.

Hysteria Major and Its Differentiation from Organic Disease.—Dr. C. L. Dana of New York reported three cases of major hysteria combined with organic disease. One was that of a woman who suffered from paralysis of all four extremities, due apparently to alcoholism and neuritis, but really a typical case of hysterical paralysis with contractures. Another case was that of a woman who had fracture of the spine and crushing of the first lumbar segment of the cord with paraplegia, but who had in addition anæthesias extending over all of one side of the body, and involving the special senses with other evidences of a complicating hysteria. The third case was a tunnel accident patient who had fracture of the ribs and burning of the hand with complicating anæsthetic hysteria. The speaker divided the syndrome of hysteria into five groups: (1) Anæsthesia; (2)Paralysis and tremor; (3) Contractures; (4) Attacks or crises; (5) The mental state. The characteristics of the anæsthesias were their appearance in the hemianæsthetic type and in the segmental type. He did not believe in the so-called "spots of anæsthesia." The anæsthesias were generally diffused, but did not usually have such sharp differentiation as in syringomyelia, though the loss of pain sense was generally more complete than that of touch. There was very rarely any loss of deep sensibility with ataxia or astereognosis. The contractures when of a fixed type were very severe and persistent and rarely disappeared in sleep. They were not accompanied by pain or cramps or exaggeration or reflexes. Dr. Dana spoke at some length on the peculiar and, as he believed, characteristic mental state of the major hysterical.

Dr. Knapp did not believe that anæsthesia was a less grave and less permanent condition than the paralysis and contracture of hysteria. He had seen a considerable number of cases in which the anæsthesia was one of the chief stigmata of the disease without any paralysis or contracture. Of course, anæsthesia was often absent. He had never observed anæsthesia involving the middle segment of the body. Hysterical paraplegia was an extremely rare condition.

Dr. B. Onuf of New York had seen two cases of hysterical paraplegia, one being associated with loss of all forms of sensation in the lower extremities.

Dr. Prince agreed with Dr. Dana that isolated scattered areas of anæsthesia were extremely rare. With regard to the nature of hysteria, he believed that some time in the future it will be possible to show a cerebral localization just as is now shown in many cases of organic paralysis.

Dr. Mills said that the differentiation between the symptom-complex of organic disease and hysteria had to do with the persistence of the phenomena. In hysteria he had found a distinct feature to be hyperæsthesia rather than anæsthesia. In hysterical cases the anæsthesia is more likely to affect the proximal portion of the limb. It was rare for him to see cases of hysterical paraplegia. Persistent contractures were rare in true hysteria. They might be pseudocontractures. The deep reflexes were often exaggerated, but never extremely so without the pressure of ankle clonus. One might have anything and everything in hysteria.

Dr. J. J. Putnam of Boston was in full accord with what had been stated. When there was an organic lesion in some part of the nervous system, it was impossible to explain the anatomical distribution of the anæsthesia. He thought the anæsthesia of distal portions of the limbs could not be explained on anatomical grounds.

Dr. Joseph Fraenkel of New York mentioned the fact that in organic anæsthesia the skin reflexes were absent in that area, while in hysterical anæsthesia the reflexes were usually increased.

Dr. Dana, in closing, said that he firmly believed major hysteria could be recognized and differentiated from organic disease. Organic disease did not present a picture like this, and it was time to accentuate that fact. The statement that hysteria might simulate everything was not true. It was quite common and characteristic, however, to have a reduction of the tactile sense in hysteria.

Focal Lesion of the Upper Cervical Cord.—Dr. F. X. Dercum of Philadelphia reported a case of progressive paralysis of all of the extremities from a focal lesion of the upper cervical cord.

Raynaud's Disease.—Dr. B. Onuf of New York read a paper on this subject with special reference to the etiology, pathogenesis, and nosology.

The Mechanism of the Plantar Reflex.—Dr. P. C. Knapp of Boston read a paper on this subject, in which he stated that the normal plantar reflex was dependent upon a reflex arc extending to the cerebral cortex, and disappeared when a certain portion of that arc was destroyed. A wholly new reflex (the Babinski reflex) might take its place under such circumstances. He also spoke of the crossed plantar reflex, and its possible significance, when the normal uncrossed reflex has disappeared.

Dr. Walton was in full accord with the present views that crossed reflexes depend upon the diffusion of stimuli through the commissural fibers in the cord, and in the pons and subthalamic region, without reference to the cortex.

Cerebral Abscess.—Dr. William M. Leszynsky of New York read a report and exhibited the brains from two cases of cerebral abscess. The first case was that of a woman thirty years of age. On admission to the hospital there was evidence of purulent mastoid disease, which was successfully subjected to surgical operation. One week later there occurred headache and a general convulsion followed by hebetude. The next day she had nine general convulsions and remained semicomatose for several hours. The pupils, optic axes, and eye-grounds were normal. There were no signs of focal brain disease. The temperature ranged from 100° to 103° F., pulse 82 to 112. The following day she was able to answer questions, the hebetude cleared, she took nourishment well, and the pulse and temperature became normal. She remained in a clear state of mind for five days and seemed to be improving. She then gradually became comatose and died. On account of the decided improvement, exploratory operation had been delayed. The autopsy revealed an otitic abscess in the left temporosphenoidal lobe communicating with a larger abscess cavity in the frontal lobe.

The second case was in a man thirty-one years of age. After exposure to cold there had been chills, fever, profuse sweating, severe frontal and temporal headache, followed by acute rhinitis, and cough with slight mucous expectoration. Six days later he entered the hospital. There was no history or evidence of ear disease. Temperature, 102°; pulse, 98°. There was extreme tenderness over the frontal bone and a mucopurulent discharge from the left nostril. Both frontal sinuses were opened, but no pus was found. Leszynsky saw him the following day (one week after admission to the hospital). He was much emaciated, with a rapid feeble pulse, and in a condition of marked mental hebetude. There were motor aphasia and right hemiplegia with exaggerated reflexes andankle-clonus. The diagnosis was made of a cerebral abscess situated either in the frontal or temporal lobe on the left side and immediate operation was advised. The operation was attempted, but not completed. Death took place four hours later. The autopsy showed purulent meningitis over the left convexity, involving the frontal and temporal lobes, and an abscess in the anterior portion of the left temporosphenoid lobe. This abscess, probably of metastatic origin, had ruptured through the cortex, thus causing the purulent meningitis. There was no evidence of cranial bone disease. A large empyema was found in the right pleural cavity.

Partial Internal Hydrocephalus.—Dr. William G. Spiller of Philadelphia reported two cases, one resulting from partial closure of the foramen of Monro by an inflammatory exudate; the other, from occlusion of the aqueduct of Sylvius by proliferation of the neuroglia. He also spoke of the existence of intense bilateral contracture in the first case, resulting from a unilateral cerebral lesion—a condition very little known—and of symptoms of cerebellar tumor in the second case, caused by the internal hydrocephalus.

Acromegaly with Diabetes.—Dr. Adolf Meyer reported a case with the usual tumor of the hypophysis. The growth of the tumor had separated a portion of the nervous part of the hypophysis from the rest which remained connected with the tuber cinereum.

Dr. Meyer also reported six instances of a peculiar terminal disorder in cases of melancholia, depressive hallucinosis, and alcoholic-senile delirium. After a course not different from that in other cases, the patients developed weakness, rigidity of all the muscles to passive motion, and a jerking tremor and grimacing, usually with diarrhœa, irregular temperature, accentuation of the delirious condition and, finally, termination with bronchopneumonia. It was not unlike certain forms of gastric tetany. The condition was one of parenchymatous alteration, chiefly of central elements, analogous to what happens in the peripheral nerves in parenchymatous peripheral neuritis, and for the sake of brevity the provisional term central neuritis might be used. Whether the disease begins in the fibers or the cell-bodies, or whether a definite toxic agent can be found, must be left to further investigation.

Arteriosclerosis of the Spinal Cord.—This was the title of a paper by Dr. William Hirsch of New York. He considered arteriosclerosis of the spinal cord a condition which is only rarely diagnosticated. The clinical symptoms might vary according to the affection of the blood vessels. The anterior half of the cord was apt to suffer more from sclerotic changes in the arteries than the posterior part, and the lower more than the upper part. This was due to the peculiarity of the blood supply of the spinal cord, the anastomosis of the posterior half being more abundant than that of the anterior half, so that in case of an obstruction the cells could derive their nutrition from other sources. Nine cases were reported in which the diagnosis of spinal arteriosclerosis was made during life. Some of them were combined with sclerosis of the cerebral arteries. In one case an autopsy was performed, which revealed arteriosclerosis throughout the entire central nervous system. The motor cells of the anterior horns showed a marked increase of pigmentation, while the cells of the posterior horns appeared perfectly normal.

Dr J. J. Putnam said that such cases had been described in a group of cases seen by him. Atropic optic nerves were observed once or twice in diffused spinal degeneration.

Dr Spiller had been interested in this subject for several years. He said that the reader of the paper had not spoken of paralysis agitans which had been regarded as a senile form of disease. In many such cases he had found arteriosclerosis. He was surprised to hear it said that the anterior half of the cord was more affected than the posterior, for that had not been his experience. Sometimes, undoubtedly, there was an arteriosclerosis in the lower extremities, but that could hardly be explained by any greater involvement of the lower portion of the spinal cord.

Dr Leszynsky said that in people at an advanced age and in others with arteriosclerosis it was not unusual to find evidence of degeneration in the peripheral nerves. This would often explain the loss of the knee-jerks and many other symptoms affecting the lower extremities. In his opinion it was always safe to make a diagnosis of spinal arteriosclerosis in the presence of generalized arteriosclerosis.

Dr. Hirsch, in closing, said he did not mention paralysis agitans because it could be excluded in the differential diagnosis.

Acute Hemorrhagic Cortical Encephalitis.—This was the title of a paper by Dr. Herman H. Hoppe of Cincinnati. He said that the study of cortical encephalitis was more necessary and of more practical utility than that of Wernicke's form of pontine encephalitis. The cause of the disease was usually one of the acute infectious diseases, measles and influenza being the most frequent, the bacillus of the later disease having been found in the hemorrhagic areas. Alcohol, ptomain poisoning, and the various metallic poisonings were doubtful etiological factors. Early childhood was the most frequent age. The clinical history was illustrated by three cases: Case 1. Acute hemorrhagic influenza encephalitis, ending in death on the fourteenth day. Case 2. General delirium with aphasia and paraphasia, paresis of right side of face and arm; recovery with defective speech. Case 3. Complication in third week of typhoid fever. Sudden onset of delirium with hallucinations. Paresis of right side of face, tongue and arm. Amnesic aphasia. Recovery with defective speech.

Dr. Mills said that the diagnosis of true encephalitis was not always made by the clinical history. The diagnosis of toxæmia without a true encephalitis would better explain several of the cases recorded as occurring in connection with typhoid fever. He would not regard cases as encephalitis, which, on post-mortem examination did not show the evidences of that condition.

Division of the Posterior Spinal Roots for Amputation Neuralgia.—This was the report of a case by Dr. P. C. Knapp of Boston, who said that this was sometimes the only effectual operation, but it was not devoid of danger. His case resulted fatally. Removal of neuromata or resection of the nerves sometimes gave no relief, and degeneration in the distal end of the severed nerves was not complete. There might be preservation of sensibility with relief of pain after division of the four posterior spinal roots.

Dr. Spiller had seen a case almost exactly like the one just reported. The man had had an injury of the upper limb, which had been amputated near the shoulder. Three operations had been done for the relief of pain in the stump. There were also involuntary jerkings in the stump. Division of the posterior roots was advised, but the operation was not urged, for it had been shown to be serious. One patient died upon the table, and another was not benefited.

Herpes Zoster and Paralysis.—Dr. P. C. Knapp of Boston exhibited diagrams of a case of zoster, with eruption, hyperæsthesia and degenerative paralysis in the region, supplied by the fifth and sixth cervical segments.

Third Day—Saturday, June 7.

Pseudoepilepsies and the Relief of Some Forms by Thyroid.—This was the title of a paper by Dr. William Browning of Brooklyn. Details of a few cases were given and some of the points made were summarized as follows: In the young there occurred a class of cases characterized by recurrent attacks of heterogenous type, that might be called "pseudoepilepsy." This form of trouble was curable. The cases studied were due to, or associated with, disturbances in the general tissue metabolism of the body. Some of these were in whole or in part of rachitic origin. Troubles of this kind when due to rachitis were amenable to thyroid treatment. True epilepsy was not remedied by thyroid, even in a person who was once rachitic. It was evident that in many cases there was a closer relationship between rachitis and athyreosis than had heretofore been recognized. There must be a relative inadequacy of the thyroid function in these cases associated with rickets. Either, as one of the cases indicated, there was a serious impairment of the activity of the gland, or thyroid feeding served to burn up harmful material at large in the system.

Dr. E. D. Fisher of New York said that children without real symptoms of myxœdema or cretinism seemed to improve under thyroid treatment. He thought the use of thyroid was deserving of trial in the class of cases reported by Dr. Browning.

Dr. Langdon expressed the view that in such cases of epilepsy, the convulsions not being due to injury or to a toxæmia, occurring in the developmental age, were, in some measure, due to defects in the neuron, or a chemical condition. The phenomena seemed to indicate a defect in structure and improvement or recovery might be hoped for after complete development.

Dr. J. J. Putnam referred to the case of a girl sixteen years old who had been treated with bromides for so-called epilepsy. When she came under his care, he found in association with her convulsive seizures a condition of ichthyosis. After the ichthyosis had been vigorously treated for a few days locally and with thyroid extract, and cessation of the bromide treatment, she began to improve, and the interval between the seizures increased by several weeks. He was of the opinion that so-called p psy was often the result of nutritional changes. These a s should not be classed as epilepsy until the conti ive habit had lasted long after the original cause has e eliminated.

ychomotor **Epilepsy.**—Dr. Ira Van Gieson of New Y k read a paper with this title. The work had been ca ied out at the Pathological Institute of the New York St e Hospitals under his directorship. The research c isted in reinstating into the patient's consciousness a ries of upheavals of subconscious intervals, accompa ied by classical manifestations of epilepsy of which th e was complete amnesia. The case related to a man th ty-three years of age, who some months before coming u er investigation had been having progressively freq nt attacks of epilepsy and occasional attacks of p t mal. The attacks were preceded by an aura, con- ng of a foul taste in the mouth with a bad odor. At t time of admission there was also a tendency toward c tinuous amnesia in the epileptic interval. Under h nosis patiently carried out, the man succeeded u esurrecting the psychic content of the first attack, all o which it was possible to verify from eye-witnesses. I vas found that the aura had its genesis in the patient's t ing a piece of stale meat from a lunch counter and u nis falling in the epileptic attack immediately afterw d. As one by one, starting from the first attack, the s sequent ones were thus synthesized into the patient's c sciousness, the new attacks became correspondingly f er. In all, about fifty of the attacks were reassociated w h the patient's consciousness. As the series of fusion b ame complete the attacks disappeared, the confusion a l mild stupor in the interepileptic periods vanished, l for some months the patient had been back at his w k and had had no attacks. The speaker announced t t a volume of the Archives of Neurology and Psycho- hology would shortly appear containing a detailed ac- c int of this case.

nsanity with Peculiar Motor Manifestations.—This was t title of a paper by Dr. H. A. Tomlinson of St. Peter. e paper dealt with the motor manifestations in three c es of insanity, which simulated those resulting from c ganic disease. They illustrated in an extreme degree t usual forms of motor disturbance among the insane. udocatalepsy, spastic tremor, and subsequent rigidity i the first case illustrated the irritative form; while ndness and paraplegia in the second case illustrated e paretic form. The entire annihilation of speech and luntary movement in the third case, which was that of idiot, suggested the pathology of these forms of motor volvement and their mode of origin; while the complete tor recovery in all of them showed that the functions the motor area may be seriously interfered with, or most entirely annihilated without permanent lesion.

New Members.—The following were elected to mem- rship in the Association: Dr. Leo S. Newmark of San ancisco; Dr. Harold N. Moyer of Albany, and Dr . E. Paul of Boston.

Election of Officers.—*President,* Dr. James W. Put- m of Buffalo; *Vice-Presidents,* Drs. C. E. Riggs of St. ul. and H. M. Thomas of Baltimore; *Council,* Drs. W. Bullard of Boston, and Joseph Collins of New York. *tary* and *Treasurer,* Dr. G. M Hammond of New rk

---

Retraction of the Palmar Aponeurosis in the Insane.— . Féré and Martha Françillon have found this symptom fourteen out of 226 patients admitted to the insane lum. It was also found in cases of general paralysis, t less frequently. A very few cases have been re- rted in epilepsy. In imbeciles there were three cases t of sixty-nine. The authors hold that in all these e retraction of the aponeurosis of the palm is a mani- tation of a congenital anatomical defect.—*Revue de decine.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending July 19, 1902:

	Cases	Deaths.
Measles	201	8
Diphtheria and croup	225	40
Scarlet fever	134	23
Smallpox	15	3
Varicella	20	..
Tuberculosis	253	146
Typhoid fever	74	18
Cerebro-spinal meningitis	..	..

The Influence of Intestinal Bacteria on Nutrition.—Max Schottelius mentions the investigation of Duclaux, who showed that the synthesis of organic substances in plants can take place only in the presence of bacteria. If sterile but otherwise healthy seeds are planted in sterile soil growth takes place only to the extent corresponding to the amount of nutrition already contained in the seed plus the absorption of water, and the plant dies at the end of twenty to twenty-five days, while other central seeds germinating under normal conditions have acquired two to three times their original weight. The fact that of the myriads of microorganisms inhabiting the mouths and intestinal tracts of mammals and particularly of man, only very few are susceptible of cultivation, makes a condition almost akin to symbiosis probable, and is *a priori* evidence of their value to the host. That this is actually so is shown by the author's experiments with sterile chicklets raised under absolutely sterile conditions and kept so until death occurred. None of these animals lived longer than thirty days, most of them dying much earlier and all lost weight steadily, the deficit in one case amounting to as much as 32 per cent. of the weight on hatching, while the control birds flourished and gained up to 117 per cent. The sterile birds appeared to be constantly hungry and ate incessantly, at the same time producing correspondingly large amounts of excrement, but, in spite of this activity and the digestion of their food by the body juices, did not grow but continued steadily to lose flesh and strength. The addition of a little of the excrement of normally-raised birds to their food, however, almost immediately produced a change and allowed their metabolic processes to progress naturally.—*Zeitschrift für diätetische und physikalische Therapie.*

Surgery of the Spine.—Eugen Hahn, in discussing the difficult question of whether to operate at all in injuries of the vertebræ and, if so, when, says that compression through fractures of the arch requires immediate intervention. If the incision shows that no fracture is present one must remain content with the mere exploration. In fractures accompanied by compression, dislocation, and crushing through of the cord, all operation is hopeless. As long as the suspicion exists that the case is one of contusion with hemorrhage no operation is permissible. In paralysis through fractures, with compression and narrowing of the canal, the attempt must be made to free the cord from pressure by laminectomy. This is to be done by the removal of the arch of the vertebræ lying above the fractured body, as the narrowing is nearly always produced between this portion of bone and the upper posterior edge of the fractured body. It is only when this measure proves unsuccessful that the much more serious procedure of removing the projecting angle of the body should be adopted. In this case the cord must be pushed aside to permit the chisel to cut away the prominent edge. The greatest judgment is required in cases of fracture of the body. The decisive point is the conviction that no improvement can follow non-operative measures

All cases in which any improvement is noted before operation prove nothing for the value of the operation, and the more favorable statistics of late surgery in such instances are easily explicable, since the cases that succumb to the initial severity of the injury are eliminated. —*Deutsche Zeitschrift für Chirurgie.*

The Etiology of Relapsing Fever.—Justin Karlinski, who has had unusual opportunities for studying this disease during a recent epidemic in the Bosnian border, believes that he has found the carrier of infection. The disease is notoriously proletarian, and in the present epidemic out of one thousand cases but two occurred in those of the better class, and even these were patients who came into continual contact with the filthy and almost brutish peasantry. The dirtiness of their homes and, in particular, the prevalence of bed-bugs, lice, and fleas are almost incredible, since these vermin are never killed, but are regarded as a special favor sent by Allah to promote health by removing poisonous juices from the body. The author examined the intestinal contents of one hundred and twenty bed-bugs taken from the infected houses, and in every case found abundant living spirilli, which corresponded in every particular with the characteristic organism of the disease. A similar examination of insects taken from non-infected houses invariably gave negative results. Fleas and lice never acted as hosts for the spirillum. The author's theory is that a bug filled with infected blood from a patient wounds the skin of a healthy individual for the purpose of further feeding, and deposits excrement in the immediate vicinity of the puncture, thus affording a most favorable opportunity for inoculation. He attributes his own escape from infection to the fact that he constantly kept his clothing and skin impregnated with insect powder during his visits to the infected localities.—*Centralblatt für Bakteriologie, etc.*

A New Protective Dressing.—Karl Springer describes a new protective dressing, which is intended especially for use in plastic operations, skin grafting, etc., where it is important to keep the dressing from adhering to the surface of the wound. The various materials, such as rubber tissue, oiled silk, oiled gauze, etc., which are in general use for this purpose are open to the objection that they stand sterilization by heat but once, after which they must be preserved in some antiseptic solution, which often impairs their strength or pliability, and always requires washing off in sterile water to remove before use. The substance which the author employs as a substitute is paraffin of a melting point of 45-47° C. If a small piece of this is thrown on the surface of boiling water it is first melted, and then, on cooling forms a thin, floating pellicle, which may be handled with forceps and cut to the proper shape with scissors. The technique of its practical application is simple. A flat vessel provided with a cover is partially filled with water and brought to a boiling point. A piece of paraffin is then thrown in and the boiling continued for ten minutes. The vessel is then placed in another dish of cold water, causing the paraffin to harden as a thin pellicle on the surface. As soon as this occurs the vessel is placed in water at a little above body temperature, which keeps the pellicle soft and pliable. Holes for drainage may then be punctured through it with a sterile needle, and after cutting to shape it is lifted with forceps and applied to the wound with the water side down. The thickness may easily be controlled as experience dictates by the size of the lump of paraffin used.—*Centralblatt für Chirurgie.*

Infusion through the Umbilical Vein.—A. Shücking, after a protracted labor, found that the usual methods failed to resuscitate the asphyxiated child. As an infusion was ready, he decided to try its effect, though the child was blue and the heart action barely perceptible. A solution of 0.5 per cent. sodium fructosate and 0.7 per cent. sodium chloride was used and the cannula simply inserted in the umbilical vein, and the cord *in toto* tied abou it. After about an ounce of the solution had entered th circulation, the heart's action improved, and after si drachms further had been given spontaneous respiratio began. This was reinforced for several minutes by Sylvester's method and then proceeded naturally, the chil surviving. The action of sodium fructosate and sodiu saccharate in such cases is the result of their taking u the carbonic acid of the blood and being converted int glucose and carbonate of sodium. In this way the embarrassed respiratory center of the child was probabl relieved and rendered irritable again, though the question involves the mooted point of the explanation of the first breath.—*Centralblatt für Gynäkologie.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health, and U. S Marine Hospital Service, during the week ended July 19, 1902:

DIET, DRUGS, AND DIAGNOSIS IN TYPHOID FEVER.*

BY CHARLES H. LEWIS,
NEW YORK.
VISITING PHYSICIAN TO ST. VINCENT AND COLUMBUS HOSPITALS.

SOME ten years ago, two patients suffering from typhoid fever entered Columbus Hospital. These patients were brought from an Italian war vessel, at that time lying in New York harbor. They were of Italian nationality, alike in build and temperament, of the same occupation—that of seamen in the Italian navy—and presumably had contracted the disease from the same source of infection. At the time of admission the course of the fever had been strikingly similar in each case, one being in the lead by about two weeks.

These patients entered the service of the late Dr. Byron, and were put upon the treatment then in vogue, viz., two to three quarts of milk, or more, in the twenty-four hours, alcoholic stimulants, and enemata when necessary to encourage evacuation of the bowels. Under this treatment these cases ran along the average lines, being neither unusually severe nor mild. Each patient had intestinal hemorrhages, and "pea soup" stools were the rule. After a rather tedious course of fever, convalescence was sighted in the first case, and recovery seemed to loom up in the dim distance. The stomach intake of milk had exceeded expectations, and the bowel output had not been unduly copious or frequent. Nevertheless, emaciation was extreme. The heart's action, notwithstanding the rather large amounts of alcoholic and other stimulation, all of which had been retained, was nothing to boast of. Yet the thought of what it would have been, or perhaps would not have been, had the stomach of the patient been rebellious, or the alcoholic supply limited, enabled me to meet this case with composure, which, although much the worse for wear and tear, had apparently run the gauntlet of a "typhoid" without succumbing. The second case was trailing along the same path, about two weeks behind the first, and receiving practically the same treatment.

These cases confronted me on beginning my service, on September 1, 1893. I continued the treatment that had previously been employed, and, in order better to combat the excessive meteorism, I recommended daily enemas, which were invariably followed by the ward note of "result satisfactory." This meant that the expulsion of the enema was attended with, or followed by, that of a very large amount of fecal matter of soupy consistence, cheesy curds, variegated color, and a most disagreeable odor, which easily and offensively permeated the entire ward.

The temperature of the first case was now hovering about the normal point. The stomach remained tolerant, and the heart, under liberal stimulation, seemed to be holding its own. After an interim of about a week, the temperature curve slowly began to rise, and the index of the general condition to fall. The unwelcome, but never unexpected, "relapse" set in. Constipation alternated with diarrhœa. Milk was poured frequently and copiously into an unusually tolerant stomach, the bowel injected regularly with high and low enemata of water, turpentine, ox-gall, etc., and, just as regularly, was recorded on the ward notes "result satisfactory." Nevertheless, continued tympanites, a failing heart, toneless and tremulous muscles, and blunted senses, pointed toward the end, which came September 20, 1893, about five weeks after the man had entered the hospital.

No autopsy was permitted, but the daily course of the disease marked out in such clear lines two pictures—the one of an apparently successful emersion from a general infection, the other a fatal immersion into a secondary intoxication—that I resolved, if possible, to change the sequence of events, and, should it become necessary, to adopt different measures in the case of the second sailor, who had been traveling, clinically, over the same road as his predecessor, and threatened to arrive at the same destination, on schedule time, about two weeks later. This patient pursued the anticipated course—an almost exact counterpart of that of his shipmate—received essentially the same treatment, and exhibited the same results.

On the advent of the "relapse," with some misgivings, but urged on by the fate of the other case, I decided to supplement the enemata with medicines administered by the mouth, and to employ what I then considered heroic treatment, in order, if possible, to lessen the tympanites, which was then extreme, and to clean out the intestines, which, judging from the discharges, were in a most foul condition; and to risk this, notwithstanding their assumed frail condition, as inferred from the previous rather profuse hemorrhages. The drug which I selected for this purpose was calomel, and the dose 15 gr., with double the amount of bicarbonate of sodium.

On the next day, on my arrival at the hospital, I ascertained a number of interesting facts: (1) That the patient had passed an enormous stool of firmly formed fecal matter, and that this had been followed by others of softer consistence, malodorous, but most tenacious and adhering strongly to the bedpan; (2) That in the formed stool were found grape skins; (3) That these must have been in the bowels for at least twelve days, as at that time the patient had partaken surreptitiously of grapes, which had been smuggled into the ward by well-meaning friends. He had been detected in the act of eating these, and the remainder had been confiscated. This fixed the time of ingestion, as it is hardly necessary to add that the patient was subsequently "saved from his friends" and no opportunity afforded for similar indiscretions; (4) The tympanites had very perceptibly diminished; (5) The general condition of the patient was slightly improved.

This called a halt in the discouraging train of ymptoms. The sequence of events took an upward turn, and very gradual, but progressive, improvement ensued. Calomel was given in large and small doses at irregular intervals, whenever the exigencies of the case demanded it. The threatened "relapse" came and went with less severity than usual, but about the average duration. After a long and tedious convalescence, a complete recovery resulted, and the patient left the hospital February 26, 1894.

---

*Read, in part, before the Hospital Graduates' Club.

From that time on, without theorizing as to the primary seat of the disease, even admitting, for argument's sake, that typhoid fever exists without intestinal lesions, I ceased to put my trust in enemas, and began to use calomel and other drugs, in varying doses, for the purpose of relieving tympanites and cleaning out the bowels, and I can truly add, with "results, both immediate and remote—satisfactory." The conclusion also has been gradually, but inevitably, forced upon me that both of these conditions were the more promptly and permanently obtained, the more regularly the dose was administered, and the smaller the amount of nourishment ingested. Another impression dawned upon me also, viz., that emaciation seemed to be independent of the amount of nourishment taken into the stomach. The system apparently assimilated, or at least accounted for, but a small part of the food intake, while the balance was thrown off by the bowels, and to a lesser extent by the other emunctories, at a cost of considerable fever, heart force, and general wear and tear to the system. After considerable clinical experimentation, carried on in conservative lines, for the past year and a half, I have selected calomel as the drug par excellence for relieving tympanites and cleaning the bowels, in half-grain doses twice a day; and one pint of milk, diluted with an equal quantity of vichy, as about the proper amount of nourishment for a typhoid patient during the twenty-four hours. The imbibition of water, preferably acidulated with dilute hydrochloric acid ʒ ss - ʒ i to a quart, is encouraged as much as possible. In my experience, too much cannot be taken; too little may be.

In hospital practice, as soon as a tentative diagnosis is made and without regard to the stage of the disease, five or ten grains of calomel with double the amount of bicarbonate of sodium is given, and the appearance of the stools and condition of the abdomen following this prescription determines a repetition of the dose, or the amount of calomel to be started as a routine measure.

Stimulants and sedatives are employed to meet presenting symptoms, not prospective ones, and are never given routinely, or without direct indication. Salol, beta-napthol, bismuth, salicylates, carbolic acid, and all the so-called intestinal antiseptics have not appealed to me on practical or theoretical grounds. In doses employed they do not antisepticize the bowel, and if they did, it would not stay the disease. The typhoid bacilli in great numbers have long before migrated from the bowel, and are lodged, proliferating, and manufacturing their toxins in the intestinal coats, mesenteric glands, spleen, and many, perhaps all of the other organs of the body. They have been found in the blood, urine, saliva, and perspiration. To the infection is added an intoxication, and the local lesions in the intestinal mucous membrane—the parts accessible to the alleged antiseptics—only mark the damaged portals of entry for the germ causes of a constitutional affection.

There may be a future for the serum treatment, but Elliot and Washburn's experience (*Lancet*, January 18, 1902) in 211 cases does not encourage much hope in this direction at present. From the nature of the disease, when the curative serum comes, it must attack primarily the bacilli, rather than the toxins.

One grain of calomel then, in divided doses, with one pint of milk properly diluted, every twenty-four hours, acidulated water, the more the better, constitute the routine diet and drug treatment which I have employed in most of the ninety cases here tabulated, and the remainder, with very few exceptions, received drugs and diet, approximating to this standard; but it is hardly necessary to add that variations and additions have been made to meet the requirements of individual cases. "No symptom is too irregular for typhoid," and the success of the physician is commensurate with his ability to anticipate or promptly meet all such unexpected contingencies. For instance, one-half grain of calomel, one or three times a day, may be advisable, according to the condition of the stools; or a discontinuation of it altogether, in the event of a stomatitis, or other individual idiosyncrasy. In such cases a laxative pill of nux vom., bellad., colocynth co., and aloes—the laxative pill of the Roosevelt Hospital formulary—twice a day, with or without a saline mixture, forms a good substitute. In general, a remedy which takes some time to act is preferable, in my opinion, to a saline used alone. Very probably cascara, podophyllin, or any other similar drug, would serve as well, but I have been habituated to the above, and they seem to answer every purpose. Enemata are exceptionally indicated.

In regard to the nourishment, there are no hard or fast lines as to quality; the quantity must, however, be limited. A good rule to observe is to consult the patients' taste, and if they have no decided preference, give milk. When the quantity to be taken is limited to a pint or less in twenty-four hours, it is rare to find any strenuous objectors. An egg, broths, or any mixed diet, may, perhaps, be permitted, so long as the quantity is limited. What may suit one may not suit another, and certain individual dietary experiments most carefully conducted may be advisable in exceptional cases, but I have never been obliged to resort to such measures. A small amount of coffee in the milk will render it more palatable to some patients.

At St. Vincent's and Columbus hospitals, in my service, each patient has his supply of acidulated water, and it is given freely. I know of nothing better to make a dry tongue moist, or a foul mouth clean. Intestinal hemorrhage, which has been a rare complication in my cases, forms no contra-indication to the calomel or laxative treatment. Ten grains of calomel and twenty of sodium bicarbonate will stop a slight hemorrhage of the bowels, as I have often demonstrated. In profuse hemorrhages opium, acetate of lead, turpentine, the ice coil, etc., may be useful. I have, at present, under treatment at St. Vincent's Hospital a private patient who has had twenty-three hemorrhagic stools extending over a period of seven days, including two days before admission. On admission—the third day of the hemorrhages—one pint of a 10-per-cent. solution of gelatin, containing also acid. hydrochlor. dil. and calcii chlorid. āā ʒ ss. and whiskey, ℥ iss., was administered during every twenty-four hours. This, with gr. ss. calomel b.i.d. and plenty of water, constituted all ingesta for five days, at which time the hemorrhages ceased. Peptonized milk ℥ viii. i.d. was then added, and the amount doubled seven days later, when the gelatin was discontinued. At present, nine days later, there has been no recurrence of the hemorrhages, and the outlook for a rapid recovery is bright. ʒ ss-ʒ i of tincture of the chloride of iron to one quart of water, instead of the acidulated water, is recommended when hemorrhages occur; and chlorate of potassum ʒ i to a quart of water in cases of stomatitis. Stimulants are rarely required.

I have thought best to make tabulated records of the cases upon which the treatment recommended in this paper is based, in so far as it affects diet and drugs. The cases were taken in regular order as they occurred in my services at St. Vincent's or Columbus Hospital. Most of the patients were under my personal observation during their entire stay in the hospital. Some were left in the fever, or period of convalescence, under the charge of the house physician, with directions to continue the treatment. All of these recovered without any unfavorable symptoms. Of those patients handed over by the visiting physician preceding me, none are included, except a few who "relapsed," or whose condition demanded change of treatment, and that on the lines indicated in this paper.

As may be seen on going over these tabulated cases, and still more clearly had I gone back prior to 1899, the tendency has gravitated toward diminishing the intake of nourishment, and a more constant use of calomel, on account, primarily, of my growing confidence in these measures to relieve meteorism. Tympanites will bear more careful watching than temperature, and in my experience, a distended and inflated abdomen is more to be feared than a temperature of 105° or 106°. An ice bath will reduce the latter, and what is more important, add tone to the system, But the difficulty of relieving a tense and baloon-like abdomen increases directly with the amount and duration of the distension, and the time soon comes when it is well nigh impossible. Nor is this difficult to understand when we consider the effect of stretching muscular tissue. If paralysis follows stretching of the sphincters, the same condition must obtain after continuous distension of the muscular walls of the intestines. Then, too, the tense intestinal wall not only interferes with peristalsis and invites septic absorption, but predisposes to hemorrhage and bowel perforation. I do not remember to have seen an intestinal hemorrhage of any considerable amount with a relaxed abdomen, although I do not doubt that such cases may occur—in typhoid all things are possible—but the picture of an abdominal coil assuming a balloon shape in order to conform to a hollow and distended belly, is so intimately associated in my mind with hemorrhage that the conditions seem supplementary.

It is then, with the idea primarily of lessening tympanites, that I have resorted to the comparatively small amount of nourishment advocated in this paper. Granting that it does this, is the amount sufficient for nourishment? Osler recommends three pints of milk, and Dreshfield in Allbutt's System, two to three pints in twenty-four hours. A. A. Smith says it is an error to give too much milk. Two or three years ago, I remember a discussion which took place in the medical section of the Academy of Medicine, and after the opinion had been pretty unanimously expressed that milk, from two quarts per day up, the more the better, should be poured down the typhoid patient, one gentleman rose and stated that he had used no nourishment at all in his cases, but plenty of water, and cited three or four cases treated by this method with 100 per cent. of survivals. Between these two extremes, a golden mean, varying perhaps with each case, must lie. At all events, the question of diet for sick and well is undergoing considerable change, and the trend of opinion is, according to the recent writings of Sir Henry Thompson and Osler, toward a lesser quantity, in order to secure the best results for a sound or ailing body.

In this connection I have abstracted brief quotations from a letter recently received by me from Dr. V. Zolnowski, in which he cites four cases treated in his sanitarium on low or no diet.

Case I.—"O. C., age twenty-seven years, suffering from gastritis, headache, and general malaise. Fasted ten days. Took nothing except water. Walked three to five miles and exercised in gymnasium two hours every day. Lost fifteen pounds. At expiration of fast expressed entire relief from above symptoms."

Case II.—"J. S., age thirty-five years; diag. neurasthenia, mental depression, catarrhal gastritis and malassimilation. Took one meal each day at 5 P.M., with hot water and an orangeade in the morning. Walked six miles per day with two hours' work in the gymnasium. Followed this up for one month, when he said he felt 'like living again.' Depression disappeared, and organic functions became normal."

Case III.—"T. D., age twenty-nine years; diag. catarrhal gastritis, insomnia and constipation. Fasted twelve days. Water given freely. Walked three miles each day for eight days, with light gymnasium work and short walks during rest of fast. Lost seventeen and a half pounds. Regained seven pounds four days after breaking fast, and looked and felt absolutely well."

Case IV.—"J. F., age twenty-five years; diag. neurasthenia, mental depression, and insomnia. Fasted eighteen days. Walked three miles daily and took light gymnasium work. Lost eighteen pounds, which he rapidly regained after breaking his fast. Slept and felt well during rest of time at sanitarium."

I regret that I cannot give in figures the exact loss of weight sustained on the restricted diet, recommended in this paper through a two to three weeks' course of typhoid. But, so far as my observation goes, it is not extreme, and patients emerge in astonishingly good condition, as I have often demonstrated.

A glance at the tables will show that when an increase is made in the diet, it is made progressively and rapidly. The returning appetite, moist tongue, retracted abdomen, rather than a normal temperature, set the time for increasing the quantity of food, and the patient's palate fixes the quality. A soft egg, bread, toast, beef broths, scraped beef, jellies, ice cream, or an increase in the amount of milk, is permitted, without any *a priori* considerations as to food value. No relapses have occurred in the cases treated by this method from the beginning, and under this management none is expected. This list also includes three cases of pregnancy, in none of which was there any interruption or any untoward complication of the disease.

As to the use of cathartics or laxatives in typhoid fever, I think the question may be fairly stated as, at present, a mooted one, with the general trend inclining toward their use. There are many and distinguished practitioners, who still advise against the employment of anything but enemas as a routine measure during the course of the disease. Osler permits Hunyadi or Fredrichshall exceptionally, repudiates the intestinal antiseptics, and admits having had no experience with mercurials. He is opposed to the eliminative theory as advocated by Thistle on theoretical grounds It may also be exceptionally true that typhoid

exists without intestinal lesions, but a few years of bacteriology has not yet wiped out the clinical and pathological experience of the best observers of a century, and, furthermore, Opie in the *Johns Hopkins Bulletin*, of last July, after a most thorough analysis of all the reported cases of "typhoid without intestinal lesions," reduces the number to three, possibly to five, and concludes, even these do not demonstrate that the organism entered the system by any other way than the intestinal canal; while the other cases simply emphasize the fact that the lesion may be so slight as not to be recognizable at the time of autopsy or may have healed ante mortem. He therefore confesses to a well-founded skepticism, as to whether typhoid ever exists without some intestinal lesion, and Dr. Welch in the subsequent discussion, while not denying the possibility, justifies Dr. Opie's skeptical views.

As to the practical value of calomel, without formulating any theory as to its advantage over other drugs, if indeed I have any theory to offer, I can only add that I have found it, after comparison with other drugs, the most useful. The patients run a smoother and more uniform course under its use. A stomatitis, of course, contraindicates its continuation. I have seen it stated, however, that typhoid patients bear mercurials better than the normal individual, and my limited experience bears out this statement. There is nothing new in the use of mercurials or laxatives in typhoid fever. Fifty years before the time of Woodbridge and Thistle, Thomas Watson recommended two grains of calomel three or four times a day in the first stages of typhoid fever "to be accompanied by Dover's powder, if the diarrhœa persisted." And, in his "Practice of Physics," quotes Dr. Latham in a comparison of two series of cases in his wards during the same epidemic, treated respectively with mercurials and liquor ammonia acetate, in which he drew conclusions strongly favorable to the former drug.

As to diagnosis, so far as I am aware, the classical symptoms of typhoid fever have undergone little change in character, number, or diagnostic importance since the time of Thomas Watson, sixty years ago. I am positive that the bedside diagnosis was made as promptly and accurately during my interne service, twenty years ago, as it is to-day; and I am equally certain that my faith was greater in the intuition of my visiting physician to "spot" a case of typhoid then, than in my own powers in that direction, now. This is, in a measure, doubtless due to our unconscious leaning on bacteriology, which has opened up a fertile field for investigation and has supplied valuable aids to diagnosis. The Widal reaction, the presence of the Eberth bacillus the specific microorganism, in the stools, urine or blood, the leucocyte count, and possibly the diazo-reaction of the urine, have forged new and strong links in the diagnostic chain.

In general terms, the Widal reaction, when unmistakably present, fixes the diagnosis; although the converse of the proposition does not necessarily follow. The often late appearance of the reaction, however, lessens its practical value for diagnostic purposes. The presence of the typhoid bacillus in stools or urine of a case clinically typhoid, may be regarded as conclusive proof of the presence of the disease. The objection of this test is the time, skill, and elaborate outfit required for the search and identification of the germ. A normal, or sub-normal leucocyte count, would tend to exclude appendicitis, liver abscess, pyosalpynx, ulcerative endocarditis, and other forms of general sepsis, but not malaria or acute miliary tuberculosis. These could, however, be recognized by the presence of the plasmodium, or the tubercle bacillus. The utility of this method of diagnosis is considerably modified by the somewhat frequent occurrence of a leucocytosis, due to complications or transient conditions, in unquestioned cases of typhoid fever. Ehrlich's diazo-reaction, which promised much, in that it is found early in the disease, has not fulfilled expectations, and in my personal experience, is of little value. It appears in about three-quarters of the cases of typhoid and in a number of other diseases as well. I am not unmindful, however, of Simon's recent recommendations, and Green's statistics, in which, with a slight modification of the test, he finds it present in 95 per cent. of his cases.

I regret that conclusions cannot be drawn from all the cases here tabulated, as to the value of the "Widal" test and leucocyte count as aids to diagnosis. Owing to unmade or unreliable tests, or misplaced records, the results of but sixty-four cases tested for the "Widal" reaction, and thirty for the leucocyte count can be vouched for. Of the sixty-four "Widals," fifty-four gave a positive reaction at some time during the disease, and of the thirty cases where the leucocyte count was made, twenty-two exhibited a normal or subnormal number (10,000 or less to the cubic mill.). These percentages agree pretty closely with the results obtained in seventy-five cases of "typhoid" treated at St. Vincent's Hospital from July 1, 1901, to January 1, 1902. I am indebted to Dr. Charles Bolduan of the house staff, under whose personal supervision these tests were made for the preparation of this list:

Total number of cases of typhoid	75	cases.
Positive Widal reaction obtained in	64	"
" " " not obtained in	11	"

(In 4 cases only 1 test made.)

Positive Widal reaction obtained on day of admission	35	cases.

PROBABLE STAGE OF DISEASE IN "POSITIVE" CASES.

Positive Widal reaction obtained in first week of disease	13
Positive Widal reaction obtained in second week of disease	24
Positive Widal reaction obtained in third week of disease	14
Positive Widal reaction obtained in fourth week of disease	2
Positive Widal reaction obtained in fifth week of disease	3
Positive Widal reaction obtained in sixth week of disease	3
Positive Widal reaction obtained, time unknown	5
	64

Positive Widal reaction obtained in *no* case, not clinically "typhoid."

WHITE BLOOD COUNTS ON DAY OF ADMISSION.

Below 5,000	7	cases.	45 cases. below 10,000.
From 5,000 to 7,000	14	"	
From 7,000 to 9,000	19	"	
From 9,000 to 10,000	5	"	
From 10,000 to 11,000	6	"	13 cases over 10,000.
Over 11,000	7	"	

Lowest white blood counts 2,200; highest, 15.600.

The mortality of the cases presented in this series is low. Not all, however, received the same low limit of nourishment and a few were given other drugs than calomel or the laxative pill. They were all, however, treated approximating to this standard. Out of the whole number of cases (ninety) here tabulated, all but three were treated in the hospital. Of these ninety cases six died, yielding a mortality of 6.6 per cent. The usual hospital mortality for all cases is from 15 to 25 per cent. (Peabody.) Of the fatal cases, Nos. 29 and 58 died, respectively, one and two days after admission. Both were hopeless from the start, and the treatment, emergency in character

In No. 29 the diagnosis was not made until autopsy. Excluding these two cases, the mortality is 4.4 per cent. No. 6 died five days after admission. He entered with tympanites, stupor, subsultustendinum, and extreme prostration. He evinced no improvement from nourishment or stimulation, which were given freely. Nos. 21 and 22 lived seven and eight days, respectively, after admission. Both were well on in the "third week" with high temperatures, weak hearts, delirium, and profound sepsis. Meteorism was extreme in each. Nourishment was given *ad libitum* and stimulation crowded without benefit. No. 21 received calomel; No. 22 none. No improvement, even temporary, in any symptom was noted in either case. No. 81, the last remaining fatal case, was one of a series of twelve cases coming from a White Star steamship, and entering my service at St. Vincent's Hospital last December. On admission, the 12th inst., the leucocyte count was 13,000; next day, 14,200; subsequent counts never below 10,000. "Widal," negative, on admission; 14th, negative; 16th, negative; 20th, positive. "Diazo," negative. The temperature, on admission, was 104 and continued about this point, never yielding to the cold baths or other treatment. The day before death three hemorrhagic stools were passed, but the patient died from cardiac failure, due apparently, to sepsis. He was in the hospital two weeks, the longest time of any of the fatal cases.

Mortality arguments, after all, are never convincing. The physician "who never loses a case," is instinctively set down as a man who never has one, or who does have a treacherous memory. The point, which I would especially emphasize, and which has often been noted by my house physicians, is the easy course which these cases run, so soon as the tympanites is relieved. The stools, one or two per day, appear with noticeable regularity and uniformity in color, consistence, and odor. The dark brown or yellow stool, not offensive odor, semi-solid consistence, of a quantity uniform in each patient, appears with astonishing regularity on the ward notes, and in case of any deviation from this standard, slight changes are made in the diet or drugs, until such a condition obtains. Hence an accurate report, or better, a personal inspection of the stools is of the utmost importance. I would rather do away with the thermometer than an inspection or careful report of the stools in a case of typhoid fever.

If I should draw any practical or general conclusions from this paper, they would be: (1) In typhoid fever, approximate the diet to a pint of milk, diluted with an equal amount of Vichy daily. (2) Approximate the therapeusis to half a grain of calomel twice a day; (3) Give free and frequent draughts of acidulated, or pure water. This is the theme. You can write your own variations.

51 West 58th Street.

The Possible Injurious Effects of Carraway Seeds.—W. Bramwell found a carraway seed in an ischiorectal abscess in an old man, the seed being in a perfect state of preservation, and, in spite of the fact that it had been lying in pus, was not even softened or swollen. The pointed extremities of many of these seeds are of needle-like sharpness, one of which, projecting from a hardened mass of fæces, could easily become fixed in the mucous membrane, and when pointing downward be driven further into it by the downward passage of the fæces during defecation, thus forming a suitable nidus for the commencement of abscess, resulting in fistula. These seeds might also cause some cases of peritonitis of obscure origin, and, perhaps, also of abscess and ulcer of the stomach, to say nothing of the irritation resulting in cancer.—*Medical Times and Hospital Gazette*

SUMMER DISORDERS, DIETETIC MANAGEMENT AND MILK SUBSTITUTES IN CHILDREN.

By LOUIS FISCHER, M.D.
NEW YORK.

When fever exists it is frequently advisable to discontinue the feeding of milk. This is also true when vomiting and extreme gastric irritability are noticed. In gastroenteric conditions we are frequently compelled to substitute other forms of feeding, owing to the intolerance of milk. Milk given in any form, be it sterilized, pasteurized, boiled, or raw, will frequently aggravate an existing diarrhœa. This is so well known that one of the first rules to insist upon in the treatment of summer diarrhœa is to "stop milk feeding." In substituting other forms of feeding, *pro tempore*, we invariably do so at the expense of body weight. It will invariably be noted that children deprived of milk will lose weight unless care is taken to substitute a proper nutritious food. The body will lose to such an extent that atrophy may frequently follow.

The following substitutes have been of especial value to the writer, and are offered for temporary use in gastric and intestinal derangements:

How to Prepare Barley Water.—This can best be made by taking one heaping tablespoonful of ground barley flour and adding the same to one pint of water. Boil this thoroughly for half an hour, then strain through cheese-cloth and add enough water to make one pint of barley water. It is advisable to sweeten by adding one heaping teaspoonful of granulated sugar. When sugar is contraindicated, as in fermentative conditions, add saccharine. When barley water is given for any length of time, and constipation results therefrom, then glycerin should be added. One teaspoonful of glycerin to each teacupful of barley water will make the same quite palatable, and will offset the constipating tendency.

How to Prepare Oatmeal Water.—This can be made by adding one tablespoonful of oatmeal flour to a pint of water, boiling the same in the same manner as above described in the preparation of barley water.

If the child is underfed, then frequently the addition of the white of a raw egg, well beaten, with either of the above-mentioned barley water or oatmeal water will be found advantageous. In like manner the writer has frequently added the yolk of an egg, well beaten, with barley water or oatmeal water properly sweetened, as a temporary substitute.

Vegetable Proteids.—Great success is frequently scored by vegetarians, especially by the use of the celebrated vegetable milks. When we consider the ingredients used, it is no wonder that they offer good temporary, and often permanent, substitutes for animal milks. The writer has frequently recommended the use of almond milk made by blanching almonds (sweet almonds) with scalding water and then rubbing them up thoroughly. One to two ounces of sweetened almonds with one pint of water will yield about one pint of almond milk. When it is to be used as the only substitute for milk the almonds can be thoroughly mashed and boiled with the water to extract all of the nutritive substance. This can best be done in the following manner: Scald about one to two ounces of sweetened almonds, removing the skin, then add about eight ounces of fresh water and mash the almonds to a pulp; boil this pulp with the water for about fifteen or twenty minutes, next strain through cheese-cloth and add enough water to make one pint. Finally add one tablespoonful of granulated sugar. This can be given *ad libitum*, depending upon the age of the child to be fed. It is certainly a very nutritious substitute for milk containing proteid.

The writer frequently uses this almond milk as a diluent to break up the curd in cow's milk instead of using cereal decoctions. When children have eczema and erythematous eruption following the use of cereals, then almond milk may be used with advantage to dilute cow's milk. It is useful as a food in urticaria.

Meat Soup Substitutes for Milk.—Another valuable substitute for milk is a good, nutritious, beef, chicken, or mutton broth. Soup broths or soups can be thickened with sago or farina, rice, or barley, in the proportion of one tablespoonful of the cereal to a pint of the broth.

Vegetable Soup Substitutes.—Mashed peas, boiled with beef or chicken or veal, offers a very nutritious proteid substitute for milk. This will be found especially advantageous during the hot summer months when milk is not well borne, and when the physician requires a nutritious food which can be fed in doses of two, three, four, six, or eight ounces at proper intervals, just exactly as milk would have been given.

Tea as a Substitute.—Weakened mixed tea is frequently of great service with or without white of egg. When children have diarrhœa and milk cannot be given, then dextrinized wheat or dextrinized barley or dextrinized rice offers a convenient and valuable substitute.

Tea with Barley Water: Coffee with Barley Water.—Weak tea, mixed with equal parts of barley water, is very valuable as a temporary substitute in hot weather. It can be fed in teaspoonful doses. It should be made palatable by sweetening with granulated sugar.

Coffee, diluted with barley water or with rice water, is very valuable as a substitute for milk when marked cardiac depression from continued diarrhœa exists.

A Few Points Concerning Milk.—When cow's milk is to be used for infant feeding a simple test can be used with advantage by almost every one. It consists in dipping a piece of blue litmus paper into the milk when it is received. If the blue litmus turns red, then it shows that the milk is acid. Such milk is entirely unfit for infant feeding, and it is necessary to add to such milk a pinch of either bicarbonate of sodium or bicarbonate of potassium. When acid milk is fed to children we will invariably have trouble.

It is advisable to learn the source of the milk, so that we can know the age of the milk received. A good plan is to procure milk which has been milked on the day it is bought. Such milk can be procured in a great many dairies in this city. Several of our largest laboratories receive milk on the morning of the milking, and hence are in a position to supply fresh milk of a low bacteria count and before fermentation is developed. It is self understood that the older the milk the more chance is offered to the development of microorganisms and the greater the tendency to fermentations. It is stale milk that invariably causes gastroenteric disturbances. When fresh milk is procured, then the same may be safely fed in its raw state, after having been warmed to the proper feeding temperature.

When milk stands for several days, as we frequently have it in New York City, then *no amount of boiling, pasteurizing nor sterilizing can destroy the toxins developed* by the colon baccillus. Such milk is a deadly poison. The experiments made by Professor Victor Vaughan of Ann Arbor, Mich., have shown that, no matter how much heat is applied to such milk, its toxins cannot be destroyed. This investigator subjected milk to a temperature of 300° F. without destroying this toxin. The toxin produced in milk is a deadly poison, and it is this toxin that is the cause of cholera infantum, which ends so fatally. It is advisable, therefore, to secure clean milk from a clean source and to feed it in clean vessels if we desire good results.

If modern sanitary methods are applied in the stables, at the creamery and, most important of all, *at the home in which the milk* is modified for infant feeding, then we have the remedy against the development of summer complaint, as well as of scurvy and rickets, which sometimes are the stepping stones to tuberculosis in later years.

FORMULA FOR WEAK INFANTS IN SUBSTITUTE FEEDING.

When vomiting and diarrhœa persist give either:

Barley water	4 oz.
Or	
Oatmeal water	4 oz.

Feed every two or three hours.

Sweeten with granulated sugar half-teaspoonful to each bottle.

If fermentation exists—colic, greenish stools, and eructations—use saccharine, ½ gr., instead of sugar for sweetening.

When constipation is caused by continued use of barley or rice water, then sweeten with glycerin by adding half-teaspoonful of pure glycerin to each 4-oz. bottle of rice, oatmeal, or barley water.

FORMULA FOR ALMOND MILK FOOD.

Almond milk	4 oz.
Granulated sugar	1 teaspoonful.

Mix. Feed above quantity, every three hours.

Whey.—To make whey, take half pint of fresh milk, heated lukewarm, not warmer than can be agreeably borne by the mouth (about 115° F.); add one teaspoonful essence of pepsin, and stir just enough to mix. Pour into custard cups; let it stand until firmly curdled; then beat up with a fork until the curd is finely divided; now strain and the whey is ready for use.

Whey prepared from fresh cow's milk should be alkaline and contain from:

0.8–1 per cent. of lactalbumin.
0.03 per cent. of casein.
1.0 per cent. of fat.

When such whey is added to milk, take of whey two parts, milk one part, for an infant under six weeks. This can be increased until equal parts of milk and whey are used. (To be used for a child several months old.)

FORMULA FOR WHEY FEEDING.

For an infant under six months:

Whey	2 oz.
Milk	1 oz.

Warm to blood temperature (about 100° F.) for three minutes, then feed. Above quantity can be fed every two or two and one-half hours.

When feeding a child two to four months old:

Whey	2 oz.
Milk	2 oz.

Feed every three hours.

If the above is well borne, we must gradually increase by adding an ounce of food; the formula will then be:

Whey	2½ oz.
Milk	2½ oz.

Feed above quantity every three hours.

The general condition of the infant—its sleep, its stool, and its body weight are important factors to determine an increase in the quantity of food.

If the child cries very much after feeding and appears hungry, then we can give:

Whey	3 oz.
Milk	3 oz.

Feed every three hours.

Some children at three months will take very readily six ounces of food. If the appetite warrants it, and the stool is homogeneous and well digested, then we need not hesitate to give the following:

Whey	3 oz.
Milk	4 oz.

Feed every three hours.

The weight is the determining factor. If the child does not thrive, increase the quantity of milk and decrease the whey.

In the case of feeble and debilitated children, I frequently order sweetened whey; instead of water, for quenching thirst. This is especially valuable in summer.

PROTEID INDIGESTION IN NURSING INFANTS.

Colic.—One of the most frequent disorders in nursing infants is colic. This colic usually appears about one hour after nursing. Sometimes it appears a little sooner, sometimes a little later. Associated with this colic there is the usual evidence of pain. The attack appears in the following manner: In about an hour after nursing the child, which up to this time has been quiet or asleep, will suddenly awake with a shriek, and scream, and at the same time draw the legs on the abdomen, get very red in the face, and continue to scream for several minutes. Such an attack will last from fifteen to twenty minutes, at other times as long as one hour. Relief is usually afforded by gently stroking the abdomen with warm sweet oil or vaselin—in other words, by using gentle massage. Besides the oil, a warm enema, consisting of warm water and glycerin, or warm chamomile tea, usually affords relief. It removes the offending and undigested casein. The stool will usually be found to contain large quantities of undigested cheese. Small white particles can be seen scattered through such stool. It is not uncommon to find, where such condition exists, that the attacks will appear after each nursing. A distinct association between the condition described and the nursing must be suspected. When this condition is suspected, then the milk must be carefully examined by a chemist to determine the percentage of its ingredients. If the percentage of casein is found excessive, then exercise of the nursing mother will be called for. Sometimes reducing the nitrogenous food and drinking large quantities of liquid will modify the amount of casein so that the milk will not be so concentrated. If the child continues with this colicky condition, in spite of this change of diet, then we must instruct the mother regarding exercise.

It is well to give the child a small quantity of oatmeal water—several teaspoonfuls will suffice—after each nursing. In other instances, giving the baby small quantities of pancreatin, or a peptonizing combination, will be found advantageous. This may be given so as to peptonize the food and aid in the digestion and assimilation of the same.

We are dealing with mother and infant, and a great many changes will be demanded. Care should be bestowed on the condition of the mother's bowels. The slightest constipation should be modified by giving her a saline, a teaspoonful of epsom salts in the morning, repeated in the evening, if necessary. She should eat large quantities of fruit, such as peaches, prunes, grapes, apples, and oranges.

Constipation.—Another result of proteid indigestion is constipation. When we are told that large, dry, cheesy curds are evacuated, then the cause of such indigestion should be sought.

If the infant is nursing, then the proper method to pursue is (*a*) Examine a specimen of breast milk, using middle milk, under a microscope; (*b*) Better yet, submit a specimen to a chemist or to a laboratory, and note the percentage of ingredients; (*c*) If there is a deficiency in the percentage of fat, such deficiency can be modified by giving the baby an equivalent of cream; (*d*) If there is a deficiency of carbohydrate, we can increase the same by giving the baby some sugar; (*e*) When there is proteid deficiency, we can modify the same by adding raw albumen (white of raw egg), almond milk, pea soup, lentil soup, or broth made from meat; whey is frequently very serviceable; (*f*) The above will give a choice between animal and vegetable proteids.

The indiscriminate feeding of cream, to strengthen the baby, cannot be too strongly condemned.

Many a dyspeptic can be traced to good mothers' and nurses' indiscriminate cream feeding.

When cream is added, and the proportion of fat or proteid is too large, vomiting will result.

The stuffing of delicate children with cream, regardless of their digestive power, cannot be too strongly condemned. When improper food is given, and the infant's stomach is overtaxed, the excess of food irritates and may cause vomiting.

If, however, the food remains in the stomach, the gastric mucosa is inflamed by bacterial fermentation of stagnant food.

This may result in fermentative gastritis and cause chronic enlargement of the stomach, or it may cause diarrhœa.

65 East Ninetieth Street.

CAUSES OF CANCER.

By ROBERT REYBURN, A.M., M.D.,
DEAN, PROFESSOR OF HYGIENE AND PREVENTIVE MEDICINE, MEDICAL DEPARTMENT, HOWARD UNIVERSITY, WASHINGTON, D. C.

The first, and probably the most powerful predisposing cause of cancer is senility, or old age, of the tissues and organs of the body. An apparently formidable objection will at once be made to the above statement by citing the well-known fact that cancer is found in young persons, and is sometimes (though rarely) congenital. Whilst this is perfectly true, yet it should be remembered that senility is only a comparative term. Many persons are practically as old in their tissues at twenty or thirty years of age as others are at sixty. The real test of old age is not the number of years the person has lived, but the retrograde metamorphosis and degradation which has taken place in the various parts of the body. When we see the arcus senilis in the eye of a patient, or note that he is suffering from fatty, calcareous, arteriosclerotic or other forms of degeneration of the organs of the body, we at once know that this person practically belongs to the class of aged persons, and this important fact must always be borne in mind in the treatment of such a patient.

This same degeneration of the tissues is often inherited, and this is, probably, the reason why the offspring of syphilitics, tuberculous patients, and drunkards often suffer from cancer at an early age. These children, there is every reason to believe, do not inherit the cancer neoplasm as such, but the resisting power of their tissues is so lessened

*Read before the Medical Society of the District of Columbia.

as to form a suitable soil for its growth and propagation.

The vast majority, then, of cases of cancer occur in persons whose tissues are undergoing degeneration, from either advancing age or senile changes. In women about the time of menopause, and in men of a similar age when the duties and labors of life begin to seem to be a heavier burden than they were in youth, this disease becomes more prevalent.

Another curious fact in the increasing prevalence of cancer during the last thirty years. Dr. Roswell Park says that if the present increase of cancer in the United States continues from 1899 to 1909 there will be more deaths from cancer than from consumption, smallpox, and typhoid fever combined. (*Medical News*, April 1, 1889, p. 399). In England cancer is also increasing. In 1898 there were 25,196 cases of cancer reported, or 902 per million of the total population. The male rate was $19\frac{6}{10}$ and the female rate was 10 per cent. greater than the average of the past ten years. (*Philadelphia Medical Journal*, April 21, 1900, p. 887). In Germany the same fact is noted: In 1898 there were twice as many cases of cancer (relatively to the total population) as there were in 1879. (MEDICAL RECORD, May 17, 1902, p. 776.) This relative increase in the number of cases of cancer is found to exist at the present time in all civilized countries, and it should be noted that this, coincident with the great improvements in the diet and hygiene of the population of our great cities, when compared with their condition during past generations.

We would not wish, however, to be misunderstood, or to assert that the increase of cancer is due to the improved hygiene and diet of the present generation, but we believe it to be due to the overconsumption of a particular kind of food about which we will speak more in detail hereafter.

Cancer *per se* is not a disease which prevails extensively in hot climates or in the tropics. Especially is it comparatively rare among those races inhabiting hot climates who live almost entirely or wholly upon vegetable foods. In Borneo the disease is unknown. Dr. A. B. Dalgetty says that he has never seen a case of malignant disease of the mamma in a native of India. He wonders whether the constant presence of malaria in these countries has anything to do with it. He also calls attention to the want of pressure upon the breasts of the Hindoo women by their thin and light clothing, and also to their habit of suckling their children until their breasts are literally sucked dry. Such a gland would appear less likely to undergo perverted action than a gland arrested while its function is still in full force. The inhabitants of certain parts of China, and Burmah suffer comparatively little from cancer, and in certain localities in these countries it is very rare. What is the cause of this comparative exemption? The facts would seem certainly to warrant the assertion that a diet of vegetable food is inimical to the development of cancer.

The second predisposing cause of cancer that we would mention is the habitual use of the various forms of alcohol as an article of diet. No one can deny the enormous amount of evil that is done to the individual who partakes of it, and also to the community as a whole by the use of alcohol as an intoxicant. But there is a more insidious and more dangerous effect upon the tissues of the body by smaller quantities of alcoholic drinks (when taken regularly) than is generally recognized. The dilute forms of alcohol enter into the blood and thence circulate through every tissue and organ of the body. What is the effect of this? The alcohol, by powerful affinity for the water of the tissues, dehydrates and prematurely hardens them. Not only this, but alcohol is a retarder of waste in the body. In other words, it diminishes the metamorphosis of tissue, it hinders the separation from the tissues of the body of those effete and waste products which should be eliminated. These used up and waste matters are retained in the body, and tissue hardening and degeneration of organs is the result. If we may use the simile, the fuel is all ready for a spark to kindle it; and if we have a local irritation, a traumatic injury, or necrosis, of the living tissue, a malignant or other neoplasm may result.

The above remarks do not apply to the drunkard; we all know what his fate will be. Many persons live daily under the influence of and die from the effects of alcoholic drinks, who were never suspected during their lives (except by their physicians) to have ever used them.

The daily use at meals of the various bitters is essentially nothing more than a thinly disguised tippling under the form of medication, and produces its dire effects in the course of time, especially when, at the same time, little or no bodily exercise is taken.

The third and most important predisposing cause of all we believe to be the consumption of too much meat and nitrogenized food. If we consider the uses of meat as an article of diet, we will speedily see that it is taken to supply the waste of the muscles and other nitrogenous tissues of the body. In persons leading inactive lives, the consumption of bodily tissue is at a minimum, and hence they need very little meat or nitrogenous food. If these same persons are habitual consumers of alcoholic drinks, even in small quantities, their power of assimilating meat is still farther decreased. In fact, as people advance toward the close of life, their needs for food, and especially for the nitrogenous parts of it, are lessened, and the amount of food given to such persons should be diminished.

Sir Henry Thompson, who is now past eighty-two, says that in old age we ought to diminish the amount of food taken; he further says that half of our ills in old age are due to overfeeding. He also advises, and has practised in his own person, total abstinance from alcoholic drinks. In persons who consume large amounts of nitrogenous food, even when they are habitual users of alcohol the frequency of cancer is greatly diminished when their avocations require them to take a great deal of exercise, or when they perform hard manual labor. In forty-six years of continuous practice I have seen very few cases of cancer (with the exception of lip or tobacco cancer) occurring among men who live in the open air. The reason, no doubt, of this is that the waste materials produced in the body are, by hard manual exercise, burnt up and consumed.

Exciting Causes of Cancer.—The theories on this subject are many and various. I shall consider at this time only three of the most important.

1. The theory of Dr. Braithwaite, who recognizes that four chief factors enter into cancer production, viz., over-nutrition, non-oxidation of ingested food, local irritations, and excess of salt in the diet. This last he considers the most important and always present, though it requires the co-operation of at least one, and probably two, of the other factors to make it efficient. The suggestion of the importance of salt as a factor came to him from noticing the infrequency of uterine cancer among Jewesses, whose religion excludes salt pork from their diet. Other considerations in favor of this

view in his estimation are the absence of HCl in the vomit of gastric cancer, the fact that salt is a most powerful stimulant to all metabolism, the local prevalence of cancer in certain districts and among certain populations where salt is a specially important element in the diet, together with an excess of nitrogenous food, etc. "Cancer-houses are," he says, "probably merely houses where there is accommodation to keep a pig and where the diet consists of a great deal of bacon, or where a great deal of butcher's meat is consumed, and with it, of course, salt, or where the inhabitants are old, but their appetites are still good; or where they are women and live well, but lead indoor lives, so that the food is not well oxidized." He believes that with the increase of cancer reported of late years it will be found that there has also been a great increase in the consumption of salt.

2. The theory of Dr. Harry R. Gaylord. Gaylord has reported that he has found the protozoon of the disease in the pathological laboratory of the State of New York. Whether his theory will stand the test, time alone will determine. Gaylord injected cancerous tissue into the jugular vein of a dog, which died twenty-two days after with a distinct cancer in the lung. He also found that the so-called cancer-protozoon and vaccine bodies developed alike when injected into the cornea of a rabbit. In his experiments Gaylord used the fluid from the peritoneal cavity of a patient operated upon for cancer, and from this obtained a pure culture of the protozoon in its hyaline form. One hundred animals were inoculated by him, and the same organisms were recovered from different organs in every case examined. In twelve animals distinct cancers were found.

3. The theory of Dr. Lambert Lack of England who believes that cancer is produced by an abnormal development taking place in normal or healthy epithelium, when invading the lymph spaces of the body. In confirmation of this theory, he adduces the results of his experiments with rabbits and other animals. In a number of cases, by introducing healthy epithelium into the abnormal cavities of rabbits, he succeeded in developing cancerous tumors. (*British Journal of Pathology and Bacteriology*, 1900, p. 154; also quoted in the MEDICAL RECORD, Sept. 1899, p. 345.)

Dr. Konstanowitch has also succeeded in producing growths not dissimilar from granuloma, and containing epithelioid and giant cells, by inserting spores of lycopodium under the skin. (*Philadelphia Medical Journal*, June 8, 1901, p. 1067.)

Whatever theory we may adopt as to the causation of cancer, there are two facts that seem to be now generally admitted. The first of these is that it is probably always local in its early stages, and the second is that its origin is due to an injury or local irritation of the part affected.

Finally the writer wishes to summarize by giving the following facts, which seem to him to express the history of the causation of cancer:

1. Cancer is a disease of senility or decay of the tissues, or at least occurs at the time when the retrograde metamorphosis of the tissues is taking place.
2. Cancer is comparatively rare in hot climates, and especially where the diet of the inhabitants is composed chiefly of rice or other starchy foods.
3. Cancer at the present time is very prevalent where animal food is largely consumed; the number of cases of cancer has been found to increase in proportion to the increase in the consumption of nitrogenous or animal foods.
4. The theory of Gaylord that cancer is caused by a protozoon or animal microorganism seems to be disproved by later investigations, and the probability is that cancer is simply erring epithelium, which has taken on an abnormal growth and development.

HUNCHBACK: RECTIFYING OF SPINAL DEFORMITY BY FORCIBLE TRACTION; IMMEDIATE STRAIGHTENING.

By J. V. YOUNG, M D.,
BEYROUT, SYRIA.

DOCTOR OF MEDICINE AND MASTER IN SURGERY OF THE ROYAL UNIVERSITY OF IRELAND AND LICENTIATE OF THE SOCIETY OF APOTHECARIES OF LONDON; LATE MEDICAL OFFICER AND SURGEON FOR THE COLONIES UNDER THE BRITISH GOVERNMENT (RESIGNED); FORMERLY ASSISTANT SURGEON FOURTH DISTRICT OF HOLBORN UNION, LONDON, ASSISTANT SURGEON TO THE ROYAL SOUTH LONDON DISPENSARY, AND ASSISTANT SURGEON AND ACTING SURGEON SAFFRON-WALDEN HOSPITAL, ESSEX, ENGLAND.

THE operation which I am about to describe will, no doubt, be of interest to the readers of this journal. To myself it is of especial interest in that it is the the first of its kind, I have undertaken and, so far as I am aware, is the first that has been performed in Syria, if not in the East.

The method and mode of procedure in straightening crooked spines were first of all put before the surgical world by Alfred Herbert Tubby, F.R.C.S., Eng., of London, and Robert Jones F.R.C.S., Ed., of Liverpool, as joint authors, in the *Medical Annual* of 1898, wherein they detailed their attempts in that direction. They pointed out the feasibility of the operation, and, writing in the same annual three years later, they have shown that their expectation of results was well-founded, and their prognoses have, in most cases, been fulfilled.

The statistics and literature that they give are briefly as follows: Up to May, 1900, Drs. Bradford and Vose report (*Annals of Surgery*, vol. xxx, p. 357) that in 610 cases operated upon for rectifying deformities of the spine there were 21 deaths. These cases were attended to by, in all, 29 operators. Of the 21 deaths 4 were due to general tuberculosis, 5 to meningitis, 4 to trauma of the operation, 3 to intercurrent diseases, and in 5 cases the cause was not stated.

The originators of the operation, Messrs. Tubby and Jones, had themselves an aggregate of 99 cases. These they divided into two series of 25 and 74, for the reason that they had another 25 cases in which manual treatment for spinal deformity had been refused, thus keeping 25 "control" cases. Of the 25 cases operated on 5 died—4 from intercurrent disease, and 1 four days after the operation, from a cause not stated.

Compare these with the 25 cases who refused operation—the "control" cases—in no one was there an obliteration of the deformity; 3 died from tubercle, in 4 abscesses occurred, 4 became paraplegic, and in the rest the deformity "steadily progressed."

Of all the 99 cases operated upon, 12 died, but only 2 as the direct result of the operation.

Acting on the initiative of these surgeons, I myself operated on the case I am reporting to this journal, and which I have aready written about to Messrs. Tubby and Jones in order to help them to complete their statistics.

I saw the case in consultation with Dr. Saïd S. Harfoosh of Beyrout about six weeks ago. I then proposed operative measures. My proposal was accepted and about a fortnight later—on the 7th of February, 1902—I operated.

The case was that of a boy, a Druse, thirteen years of age, who three years before "was running quickly beside a cow and fell violently [sic] on his back on a stone." The father says the cow kicked his son on the back. Be that as it may, eliminating any sign or symptom of tuberculous disease, I arrived at the conclusion that the case was a distinct one of injury. This makes the case the more interesting, as it points to reduction as being feasible in these cases as well as in those the results of Pott's disease, to which cases, I believe, the operative proceedings have been hitherto confined.

In operating I adhered as nearly as possible to the methods worked out by Jones and Tubby. No anæsthetic was used, and there was not, whilst the patient was undergoing the operation, the amount of pain apparent that I anticipated. The *modus operandi* is not only so well described, but so well illustrated in the articles to which I have alluded, that it may seem superfluous for me to travel so closely over the same ground again. There is nothing too good, however, to be repeated, and the slight difference in my *technique* may be my apology.

The patient was placed upon a plain deal table face downward with his chin about four inches beyond its edge—my five assistants and the nurse that was to hand the bandages being in the positions assigned them respectively. The submental and occipital bandages were applied in such a manner that a level pull could be made on the spinal column in pulling with and against the four other assistants that I considered necessary—one to each arm and one to each leg.

Dr. Harpoosh took charge of the head. The other assistants were unqualified men, professionally speaking, and I may be permitted in passing to thank Dr. Harpoosh for having previously put our four unqualified assistants through a somewhat rigorous rehearsal.

I superintended the hump myself, and, at a signal, the assistants, all together, made steady traction, beginning with a small amount and going on till I raised my hand. This was kept up for about eight minutes, during which time I was occupied in manipulating the hump and putting on a Sayre's jacket from two inches below the crest of the ilium to as high up under the armpit as was indicated.

The jacket was put on in the usual way, a rather thick jacket of aseptic cotton-wool being placed in position next the skin which had previously been thoroughly washed and asepticized by a solution of perchlorid of mercury 1:2,500. This precaution was taken for fear of lice or other insects, as I intended the Sayre's jacket to remain in position for at least six weeks.

Over the position of the original deformity a pad of cotton-wool was placed, over which the plaster-of-paris bandages were adapted—these being saturated in hot water, as I wished them to set while the patient was on—or rather off—the table.

And here comes the slight departure from the procedure usually (always, I may say) adopted. Instead of using the swing, I applied the jacket while the tension on the patient's spine was never being relaxed for a moment from the operative stretching till the jacket was in position and set.

The traction, after reduction, was sufficient to keep the body just touching the table in order to maintain the spine in its extended position, rendering the bandaging a practically easy task at the same time that the necessity for keeping the body only "in touch" with the table (so to speak) kept the assistants on the alert during a somewhat fatiguing pull.

So far as I could judge, there must have been, for reduction purposes, a pull of at least 70 kilos. (140 lbs. avoirdupois), the assistants at the leg making counter-traction to the three engaged with the head and the arms, three pulling against two.

There was a good deal of grating and "crackling," and this continued and increased during my manipulation; then suddenly stopped, when I gave the signal that the force applied was enough. With the exception of a slight knobby swelling, the deformity seemed to have disappeared. The latter was situated in the lower dorsal spine, encroaching on the lumbar. The deformity—one might call it a disfigurement—was very great, and I regret two things—that I did not have a photograph taken of the case before operation and that I took no measurements. The position the lad assumed in walking reminded me very much of that adopted by the late Edmund Booth when playing the hunchback in "The King's Jester" (I think that was the name of the play).

For three days and three nights there appeared to be a continuous aching pain. On the fourth day after operation the patient was raised by his armpits, but was unable to stand upright alone or with help.

Orders were given that he was not to lie in one position, but might be rolled over on his stomach or sides, and that he was to be lifted by his armpits and by his chin and back of his head three or four times a day. On the sixth day he was able to stand alone and walk a few steps with support.

As the organs of circulation and respiration had not apparently accommodated themselves to their new surroundings, nor to one another, I thought it better to restrain the patient's desire to "get up and walk." Nevertheless, on calling to see him on the seventh day after operation I found him walking about the room. His pulse was rather rapid, small, and weak; but the respiration was normal, so far as the jacket would permit.

On the 1st of March—three weeks after operation—I found (in opposition to my instructions, I may say) he had gone out with his father, who is a vendor of oranges. No harm seemed to have resulted; but I put my *veto* on this procedure.

It is now a month since this patient's spine was rectified, and the lad is going about now apparently straight and well, but with the Sayre's jacket on. His father, contrary to my orders, persists in taking the boy about with him, saying that now his son is well [sic] he must assist him in earning his living.

These are some of the factors we have to contend against in insuring ultimate good results in cases such as this. The father has been importuning me to take the jacket off, so that he and his son may go to their work on the mountains. Just as I am writing I have received replies from Drs. Jones and Tubby to my notes informing them of the immediate result of this case.

Mr. Jones says: "One's experience in straightening spines has at least done this good, that one ought in the future to prevent deformities from arising." And Mr. Tubby adds to his letter: . . . "The great difficulty has been to keep it (the spine) straight." . . . "Another point of great importance we found was to take as much of the weight of the head and shoulders off the back as possible . . . they are practically the gist of our own experiences.

A Sensitive Anti.—Mr. Stephen Coleridge, one of the loudest of the antivivisectionists in England, recently brought upon himself a well-deserved rebuke from a judge and jury. He brought an action for libel against a clergyman who had replied to some of his abusive letters in the press. The jury stopped the case and said the action ought not to have been brought. The judge fully concurred, and said Mr. Coleridge indulged in hard hitting himself and should not be thin-skinned.

DIAGNOSIS OF INCIPIENT CARCINOMA OF THE ENDOMETRIUM.

By J. A. SCHMITT, M.D.,
NEW YORK.

It is not unusual to see patients suffering from uterine carcinoma at such an advanced stage of the disease that an operation with a view to cure cannot be undertaken. It would be unjust to place the responsibility exclusively upon the patient or upon her physician, for cancer of the uterus may exist for a length of time without presenting any symptoms of sufficient gravity to attract attention.

Of the three subdivisions, *viz.*, carcinoma of the vaginal portion of the cervix, of the cervical canal, and of the body of the uterus, the last-named is especially marked by the uncertainty and obscurity of its initial symptoms. Let us assume a cancerous growth originating in the endometrium. The congested condition of the mucous lining in and around the affected area may give rise to symptoms of endometritis, *viz.*, a serous or seropurulent discharge, tinged with blood. This disturbance, when it befalls a menstruating woman, does not arouse suspicion, but it becomes highly significant when it occurs in a woman after the menopause. This symptom of a bloody, serous or seropurulent discharge—profuse bleeding is unusual at the early stage—in a woman whose menstruation has ceased months and years ago, is, from a clinical point of view, about the most important we possess for diagnosing a beginning endometrial cancer. All the other signs are so indistinct and general in their meaning as hardly to arouse suspicion, much less to permit of a definite conclusion. The one or the other may even be absent, though the malignant growth has existed for a length of time. Pain and enlargement of the uterus may be mentioned. Patients with carcinoma of the endometrium commence early to suffer from pain; it is varying in character, either continuous, dull, heavy, and probably due to the progressive destruction of the mucous membrane and uterine wall, the nerves of which are irritated and gradually mortified; or it may be spasmodic, labor-like, and apparently attributable to the attempt of the uterus to expel the new growth or articles of it. Both varieties of pain are not infrequently described by the patient as backache, and it is well to remember that painful sensations, though having their source within the uterus, are often referred to some other region, preferably to the back.

With the growth of the tumor a gradual enlargement of the uterus takes place. How rapidly the womb increases in size, and whether the enlarged uterus is of hard or soft consistency, depends upon the histological structure of the neoplasm. It would be preposterous to base the diagnosis of cancer upon a symptom so common to many uterine disorders; nevertheless, when a woman consults us for serous flow and uterine hemorrhages and we discover an abnormally large uterus, our first thought, after excluding pregnancy, is of an intrauterine growth of a possibly malignant nature. In incipient cancer we can hardly expect an enlarged uterus; on the other hand, we are occasionally surprised at the small size of the uterus as compared with the advanced destruction of the endometrium and of the uterine wall. In atrophic uteri, though affected by endometrial cancer, we find an abnormally small uterus.

Two other signs—fetid discharge and cachectic appearance—would give us valuable hints, if they did not make their appearance at so late a stage of the disease. To produce putrefaction, a communication with the outer air and a free passage of putrefactive germs into the uterine cavity must have been established—a condition usually brought about by a widening of the uterine canal from sloughing. The development of the intrauterine growth may have far progressed, and yet a well-preserved, rigid cervix may prove an effective barrier against intruding germs.

When we review the clinical symptoms just enumerated, we must confess that they do not enable us to arrive at a positive diagnosis. Whether we consider them singly or collectively, the result is only guesswork, which may lead us to suspect, where nothing is to be suspected, or to undervalue symptoms and to forego the advantages of early surgical interference. To test the truth of this statement, let me mention a few instances of my own experience.

A woman, fifty-two years of age, last menstruated four years ago, complained of having a sanguinolent purulent discharge of several weeks' duration. The uterus was found enlarged and painful on touch. The suspected intrauterine carcinoma proved to be gonorrhœal infection. A woman, thirty-six years of age, suffered for two months from intense, spasmodic pains and menorrhagia, and in the intervals from a fetid, brownish, purulent flow, which could not be influenced by vaginal irrigations. The examination revealed an enlarged uterus of hard consistency and with a patulous cervix, which admits the introduction of the finger just far enough to feel the lower part of a hard prominence. The patient had occasional chills and fever and an emaciated, cachectic appearance—in fact, a slow sepsis had set in. I was tempted to assume the existence of an intrauterine malignant growth, but a careful exploration disclosed a sloughing submucous fibroid.

Another case was examined and its history followed up by me. A woman, forty-two years of age, complained for three months of an obstinate, odorless sero-sanguinolent flow. Previous to these ailments she had regularly menstruated. She never had hemorrhages or labor-like pains. On examination the cervix was found to be closed and the uterus to have increased to the size of a man's fist and to be of a soft consistency. The question as to the character of the intrauterine disorder was left undecided, though the clinical history was more in favor of an intrauterine malignant growth. The patient withdrew from my observation and later on was admitted to an hospital. Here she submitted to vaginal hysterectomy, which I witnessed. On cutting open the uterus after its removal a well-preserved placenta, corresponding in size to that of a four-months' gestation, was discovered.

About three months ago a robust woman, fifty-six years of age, consulted me. Her menses had ceased six years previously; she had no pains, and was only alarmed at a bloody, sometimes discolored, nonodorous, serous discharge of six months' duration. The examination revealed a lacerated, eroded cervix, a small, retroverted uterus and hanging from the posterior lip of the cervix was a small polypus. It was tempting to assure the patient that she could easily be cured by the removal of the cervical polypus, replacement of the uterus, and an appropriate treatment of the laceration. But the diagnosis of intrauterine carcinoma was made and vaginal hysterectomy, including the removal of adnexa, performed. On splitting the uterus the interior was found to be filled out and the endometrium and parts of the uterine wall to be destroyed by the soft, villous masses of a cancerous growth.

As has been pointed out, various conditions may be mistaken for cancer of the endometrium.

The different forms of endometritis, a retained placenta, a polypus, a submucous fibroid, sarcoma of the mucous membrane, malignant deciduoma, etc. Only the last condition claims a brief consideration. Though a perfect harmony among writers on this newly-discovered disease does not yet exist, the results of careful microscopic study during the last few years goes far to show that malignant deciduoma is a cancerous growth of the epithelial lining—syncytium—of the chorion-villi. Obviously, this form of carcinoma develops in the puerperium or immediately after it, and is clinically characterized by uncontrollable hemorrhages. The practitioner should, therefore, be mindful of the possible presence of deciduoma malignum in patients, who suffer during puerperium, or at a time subsequent to it, from an excessive flow of blood, the appropriate treatment of which had not been successful.

If intrauterine disorders are so easily mistaken one for the other, what measures have we to protect ourselves against erroneous diagnosis? The only safeguard against errors lies in the systematic use of all means at our command for exploring the uterine cavity. These comprise probing the uterus, digital exploration after dilatation, and microscopic examination. It is not advisable to place too great reliance upon the result obtained by the use of the sound, though in the hands of the experienced the sound may reveal the existence of intrauterine growths and raw areas of the endometrium. But small elevations and pendulous polypi easily escape discovery; it is well, therefore, to have the diagnosis, established by means of the sound, verified by digital exploration. This is one of the most important methods of examination at the disposal of the gynecologist, but less generally employed than it deserves to be. In conjunction with microscopical investigation it accomplishes everything that is needful for a correct diagnosis.

The preliminary dilatation of the cervix may be done either by splitting or by the use of tents. The former method is best accomplished by cutting through the posterior cervical wall, including the internal os; it has the great advantage that dilatation, digital exploration, and operation can be proceeded with in one sitting, an advantage that sufficiently compensates for the subsequent trouble of repairing the cervix.

For the bloodless dilatation of the cervix, laminaria is the best; it is easily kept in an aseptic condition, and a laminaria tent of about the size of the little finger should be inserted twenty-four hours before exploration is made. By conjoined manipulation with the index of one hand in the uterine cavity and the other hand on the abdomen, the uterus is pressed against the exploring finger, and any anomalies of the endometrium, namely submucous fibroids, retained placenta, polypi, indurated areas, etc., may be recognized, and an appropriate treatment immediately be added. It is hardly necessary to mention that this method is carried out under strict antisepsis and contraindicated in the presence of inflammatory processes around the uterus.

It is of the utmost importance that the dilatation, whether by cutting or expanding, be sufficiently wide to allow an unimpeded introduction of the finger. A constriction by the cervix, however slight it may be, benumbs the sensitiveness of the finger and greatly interferes with the free movement of the finger within the uterine cavity.

Thus small infiltrations or small, soft outgrowths may easily escape discovery.

Although the digital exploration offers an excellent opportunity of determining the condition of the endometrium, it is by no means devoid of errors. Of all our senses the delicacy and discrimination of the sense of touch are the most poorly developed. Coarse pathological processes are easy of detection by the finger; the difficulty of interpretation arises when delicate changes originate in the endometrium; besides, the most important question, whether or not the detected outgrowth is malignant, is left in abeyance. Here the microscope masters the situation. A thorough curettage, including all areas of the endometrium and the microscopic examination of the removed particles, will, in most instances, decide the question. It may be asked, why not at the outset resort to the microscope as the sovereign means of research? I answer, "A positive diagnosis as to the condition of the endometrium can often be made out only by exhausting all diagnostic resources; it gives comfort and satisfaction to have the diagnosis fortified in several ways, which do not preclude, but supplant each other. Let me illustrate this statement by referring to cases in practice. A woman suffers from metrorrhagia. Curettage and microscopical examination fail to detect any pathological process; we have recourse to dilatation and digital exploration and discover a submucous fibroid or a small polypus, the presence of which had not been revealed by the sound or curette. Women near the climax occasionally suffer from profuse and obstinate uterine hemorrhages. We suspect carcinoma, but repeated curettage and microscopical examination of the scrapings fail to demonstrate malignancy. We resort to digital exploration, in order to control and supplement the microscopic diagnosis; we affirm the correctness of the diagnosis by the inability of finding anything pathological within the uterus.

It is not my purpose to go into details upon the histological characteristics of the different intrauterine affections. The description of the varied inflammatory changes of the endometrium and the differentiation of benign from malignant processes is an interesting subject, the knowledge of which can hardly be obtained by occasional observation and cursory study.

135 E. 61st Street

Inheritance of Recurrent Attacks of Jaundice and of Abdominal Crises with Hepatosplenomegaly.—Sir Thomas Bartlow and H. Batty Shaw report two cases occurring in mother and son, the special points of which are: (1) The chronicity of the affection, lasting in the son at least fourteen years, and being probably congenital, and in the mother for a much longer period; (2) The occurrence of indolent ulcers in both cases; (3) The constant presence of slight jaundice, which undergoes periodic intensification and is then associated with pain in the liver or spleen, or both; (4) The mother's would appear to be a case of Hanot's cirrhosis of the liver, while her son's cannot but be considered as an earlier incomplete stage, possibly of the same malady; (5) Finally, attention is called to the extremely guarded prognostic view to be held in such cases. Mrs. W. has grown to maturity and has had a family of several children, and but for the disturbance caused by the periodical attacks of jaundice and abdominal pains is able to enjoy life.—*Medical Press and Circular.*

Associated Epidemics.—V. Babes cites cases which demonstrate that it is not sufficient in an epidemic to find Pfeiffer's bacillus in order to affirm that we are dealing with influenza, nor does a positive serum reaction enable us to affirm that the disease is typhoid fever, for it is possible at the same time to find both these elements of diagnosis in the evolution of a particular syndrome—an associated epidemic which is neither influenza nor typhoid. From an epidemiological point of view, the facts go to show that every epidemic is not produced by a single specific microbe, but that, on the contrary, there exist particular associated epidemics, provoked either by ordinary causes, or by the associated factors, or by specific germs complicating other equally specific infective states as yet undetermined.—*Medical Press and Circular.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, August 2, 1902.

OPERATIVE TREATMENT OF APPENDICITIS.

It is somewhat of a coincidence that just at the time when the King of Great Britain was developing acute appendicitis the surgeon who was to operate upon him should have chosen "Some Phases of Inflammation of the Appendix" as the subject of the Cavendish Lecture. The question of when to operate for the affection termed in America appendicitis is so extremely vexed a matter that to pass any definite opinion would be but to step into a storm of controversy, so utterly diverse are the views expressed by various eminent authorities.

On the North American continent, and in the United States in particular, appendicitis has come to be regarded as a disease, in the experience and in the treatment of which our physicians and surgeons are leading authorities. Indeed, so conscious are many of the American medical practitioners of their superiority in this respect that they have not scrupled to criticise the operation upon King Edward in adverse terms, and to offer to Sir Frederick Treves advice which they hope he may profit by on future occasions.

While allowing that in this particular branch of surgery Americans have had greater experience and consequently, perhaps, have attained to greater knowledge and skill, at the same time the fact may be borne in mind that the well-known English surgeon is by no means a tyro so far as appendicular diseases are concerned. During the time that he was surgeon at the London Hospital with its vast field of clinical material, his opportunities were ample to study the malady in all its phases. Treves brings forward the following points in the consideration of the question:

1. In the advocacy of what may be termed indiscriminate operation it is misleading to use the expression "gangrene or rupture of the appendix," perforation of the appendix, and "appendicitis with acute peritonitis" in exactly the same sense as the terms "gangrene or rupture of the bowel," "perforation of the stomach," and "acute peritonitis" are employed in association with urgent operation.

2. The greater proportion of cases of appendicitis recover spontaneously, and it is probable that the general mortality of the disease—if examples of all grades be included—is not above 5 per cent.

3. Operations carried out during an acute attack are attended with a risk to life which is considerable, and which is probably expressed by a mortality of over 20 per cent. Certain hospital records and collections of cases appear to place the death rate even higher than this.

4. It must be remembered that relapses may occur after operation carried out during the acute stage.

5. The removal of the appendix during the quiescent period is attended with a very trivial risk, which may be expressed by a mortality of 1 in 500.

Regarding the above propositions as bases for some sort of definite action in the management of the acute case, Treves says that it has appeared to him that a reasonable course may be established upon some such lines as the following:

(*a*) He ventures to think that our knowledge of the pathology of the disease and its general mortality will not sanction the practice of opening the abdomen in every case of appendicitis as soon as the diagnosis has been established.

(*b*) Immediate operation is demanded, at the earliest possible moment, in all ultra-acute cases.

(*c*) Immediate operation is demanded in every example in which there is reasonable suspicion that suppuration has taken place.

(*d*) In cases outside those above named he thinks that the question of operation may be kept in abeyance for the first few days of the attack, and may usually be left open for decision until the fifth day or after.

Treves ends by saying that he has removed the appendix during the quiescent period over one thousand times with two deaths. The careful and conservative treatment of the case of King Edward has been attended so far with conspicuous success, and until all the facts are known there would appear to be no reason to doubt that the course of treatment taken by the British medical attendants was thoroughly justified.

ARTIFICIAL IMITATION OF LIFE.

THIS is essentially an age of scientific investigation. The mystery of life has ever possessed a peculiar fascination for the student of research, and numberless have been the attempts to discover its origin and cause. The *Academy and Literature* of a recent date contains an article by F. Legge, in which he records experiments made from remote times to now in the direction of artificial imitation of life, beginning with the observations of Paracelsus The first part of the article is taken up with a consideration of the meaning of the experiments of Paracelsus, and the writer suggests that, perhaps, the old-time philosopher, when he laid down rules for forming from certain chemicals a homunculus, which could be nourished, and even be capable of reasoning and speaking, intended to describe experiments imitating vital phenomena. Mr. Legge shows that the words of Paracelsus cannot be taken in a literal sense, as neither human nor any other form of life can be obtained as the result of chemical action, for the reason that all known forms of life, whether vegetable or animal, are not simple, but complex, being made up of cells.

The amœba, the next simplest form of life to the moneron, is a cell having a nucleus of harder albumin, an external body of softer albumin, or protoplasm, and in further evolution an outer cell-membrane which holds together the entire organism.

These cells propagate themselves when they have reached their normal maximum of growth by self-division, each half appearing in turn with the full equipment of nucleus, protoplasm and membrane, and it is from cells like these that the bodies of plants, animals and, finally, man, are compounded. If the body of man were a simple entity, as Paracelsus believed, and not a republic of cells aggregated together as it really is, it might be possible to produce a human being on the plan suggested by Paracelsus, but with our present knowledge of the composition of a living body, such an event seems the height of illusion.

Mr. Legge goes on to say that if we analyze the substance of which these cells are composed, we find that the albumin is not a simple substance or element, but is in itself a compound, made up of carbon, nitrogen, hydrogen, and oxygen, with, it is said, always a trace of sulphur and phosphorous.

But there is nothing in these elements, consisting, as they do, of the three gases and the three solids which are most widely diffused through the universe, to account for the phenomenon of life, the explanation of which must, therefore, be looked for elsewhere.

What is it that gives to the cell the mysterious powers of growth, of movement, and of reproduction? Many answers have been made to this question but it cannot be said that any of them are satisfactory.

"One small corner of the veil which covers this mystery has now, however, apparently been lifted. In a communication lately made to the Congress of Physical Science, held at Ajaccio, Dr. Leduc of Nantes asserted that he had discovered a way of forming cellular tissues artificially, and not in the way of nature. If, he says, you cover, a perfectly clean glass plate with a very thin layer of gelatin and sprinkle it with a few drops of ferrocyanid of potassium, you will see start into life a collection of cells having a regular polyhedric form, and containing each a nucleus, a sac of protoplasm, and a membrane exactly like the cell of a plant or animal. He does not, indeed, say that these artificial cells have the power of growth, movement, or reproduction that we have seen in the lowest forms of animal life, nor do I know what precautions he took against the infection, to use a convenient phrase, of those bacteria of which gelatin is the favorite field of culture. But assuming that these cells are really produced by the saline solution and the gelatin without any extraneous aid, we have, even if they be lifeless, a sort of hint of the process by which the first moneron took life. It has always been supposed that the albumin of the cell-plasm possessed a highly complicated molecular structure, although this has never been demonstrated, so far as I know, by microscopical or other examination. But cyanogen, which is one of the elements of the salt used by Dr. Leduc, in his experiment, is one of the most anomalous substances known to chemistry, because, while it behaves in all respects exactly like an element, it is nevertheless found by analysis to be decomposable into carbon and nitrogen, a solid and a gas that we have already found present in albumin. Such a quality of origin in an otherwise elemental body is found in only one other substance, namely, the hypothetical metal, which is the base of ammonia, and which, although behaving like its related metals, sodium and potassium, is known to be a compound of nitrogen and hydrogen. In this connection, too, it must be noticed that the first 'organic' substance artificially produced, viz., urea, was manufactured from the union of these two anomalous substances—cyanogen and ammonium. It may, therefore, be that at some period in the earth's history, of which they form almost the sole record, the elements known to modern chemistry were themselves formed by the union of yet simpler bodies, and that this process was, for some reason, favorable to the development of organic life. If this speculation, suggested rather than supported by Dr. Leduc's experiment, turns out to be well founded, the homunculus of Paracelsus, although it may never come to us in visible form, may yet not be such an impossible dream after all."

Experiments of the nature conducted by Dr. Leduc, while serving no directly practical purpose, are, nevertheless, highly valuable and instructive. The homunculus dreamed of by Paracelsus will never be evolved by any effort of the human brain, but such investigations are by no means useless, as all tend to the increase of knowledge, and, incidentally, may lead to valuable practical discoveries.

GREAT INCREASE OF CANCER IN GREAT BRITAIN.

A WRITER in the *Medical Magazine* for June, dealing with the causes of the death among the assured in the Scottish Widows' Fund, draws attention to the remarkable increase—exhibited in the statistics of the company—of mortality from cancer.

From 1861 to 1870 the mortality of all ages among 10,000 males was 2.42; from 1871 to 1880, 3.12, and from 1881 to 1890, 4.30.

Thus the rate of mortality for all ages was nearly twice as great from 1881 to 1890 as it was from 1861 to 1870.

Two points of interest are apparent from these tables: (1) That, as measured by the total deaths from all causes, there has been a very considerable increase in the mortality from cancer among our members during the twenty-one years. It is worthy of note that the actual number of deaths from 1888 to 1894 was more than double that from 1874 to 1890. (2) That there was a very serious decrease in the average age at death from 1874–1880 to 1881–87, and a very slight recovery in age from 1881–87 to 1888–94. This is contrary to the experience of the company for death from all causes, the average age at death for the total mortality in each septennium being 57.083, 58.105, and 59.192 years respectively.

For the twenty-one years, 1874 to 1894, from group fifty-five to sixty-five upward, the death rate of the Scottish Widows was very considerably higher than that for England from 1881 to 1890.

The following conclusions are reached by the writer:

1. The registered increase in the number of deaths from cancer is undoubted. This is proved by the statistics of the Scottish Widows' Fund, and corroborated by all other authorities.

2. After allowing that this increase is not wholly real, but may be accounted for, to some extent, on the assumption that the true nature of obscure

cases of malignant disease has been recognized with ever-increasing certainty in recent years, and that, as a consequence, the statement of death has been made with greater precision than had been formerly the case, there remains a large real increase to account for the large and progressive mortality from this disease.

3. The age period at which death from cancer is most frequent is gradually declining, according to the Scottish Widows Fund returns.

4. The average age at death from cancer among its members declined by two years in the two decades from 1874 to 1894, as contrasted with a rise in the average age at death from all causes of a little over two years.

5. The office returns mark a decrease in death from internal cancer of 7.70 per cent. and an increase in deaths from external cancer of 18.89 per cent. of the percentages in the first septennium as contrasted with the third.

The most salient point in these statistics is the demonstration of the fact that cancer as a cause of death between the ages of forty-five to sixty-five has made rapid and startling progress.

Longevity Increasing in Chicago.

Chicago enjoys the services of an excellent health officer in the person of Dr. Reynolds, a gentleman of great versatility, who is not only an energetic sanitarian but also a skilful statistician. He is a believer in the value of figures and knows how to use them in support of the arguments which he advances from time to time in the entertaining weekly bulletins issued by the department of which he is the head.

In one of the recent bulletins, that for the week ending July 5, some interesting statistics are presented showing, despite the adverse testimony afforded by the increasing number of suicides, that the inhabitants of Chicago are, on the whole, becoming more resigned to life there, now that the railroads have brought the town within twenty hours of New York.

A tabulation of the ages of 443,920 residents of Chicago, who died between January 1, 1869, and December 31, 1898, enabled the health department in its April, 1899, bulletin to show that the duration of human life in that city had increased from an average of 13.9 years at the beginning of the thirty-year period to an average of 29.4 years at the close. This is an increase of duration of life of considerably more than double—111.5 per cent.—in less than a single generation. It was further shown that if those who died in 1898 had lived only to the same average age as those who died in 1869 their aggregate ages would have amounted to 318,268 years; whereas their aggregate ages actually amounted to 672,540 years—a gain of 354,272 years in the lives of the 22,897 persons who died in Chicago in 1898.

Dr. Reynolds also shows that people live longer in the city itself than formerly. Nearly one-fifth of those who now die have survived to be upward of sixty years of age. Out of the total of 453 deaths recorded during the week ending July 5 eighty-seven averaged 72.2 years each, the youngest being 60 and the oldest 94 years 6 months 9 days. The aggregate lives of these eighty-seven decedents was 6,272 years. There were forty-six between 60 and 70, twenty-one between 70 and 80, fourteen between 80 and 90 and six over 90 years of age. Of forty-eight whose length of residence in Chicago was given the average was a little over 74 years and their average length of residence in the city was 32.7 years. The longest period of residence was seventy-two years, the decedent being 85 years 5 months 14 days old at date of death. The proportion of those who live to reach three-score and beyond is steadily increasing; the proportion of those who die under 5 years of age is even more rapidly decreasing.

The Exact Seat in the Brain of the Highest Intellectual Faculties.

Whether the prefrontal lobes of the brain contain what we term the mind, or whether the lobes in back of the head perform the best part of our thinking, is a disputed point with scientific investigators. The mass of evidence, however, is in favor of the former view, and, as pointed out by the *London Standard*, recent researches and observations by Dr. Phelps would appear to assist in strengthening the opinion that the most important portion of the brain is its anterior region. In the course of Dr. Phelps' investigations some 295 cases of brain injury and disease were examined. In all save two it was noted that interference of an extensive nature with the prefrontal region resulted in serious disturbance of the mental faculties. Less severe injury produced less marked effects.

As to the relative importance of the two lobes of the cerebrum, it is well known that each half governs the opposite side of the body, and that the left brain is superior in mental faculties to the right. Dr. Phelps not only calls attention to the unquestioned superior functional importance of our left brain, but also insists that it is the intellectual half. The fact is pointed out that the right half is capable of sustaining severe injury without the sequence of marked mental ill-effects, and instances are quoted in support of this assertion. Cases of this kind have been, on many occasions, a puzzle to physiologists, insomuch as the injury to the brain has not been attended with commensurate mental disturbance.

If it can be shown conclusively that the left brain is the seat of the intellect, and proceeding upon the hypothesis that severe injuries to the head which do not produce utter mental wreck really involve only the right lobe, then a partial explanation will have been afforded of conditions attending brain injuries which have long puzzled physiologists.

While Dr. Phelps' theories are ingenious and plausible, they are not conclusive, and much has yet to be learned concerning the brain and its working ere the last word has been said. There are, says the *Standard*, physiologists who declare that we have really two brains, and that while the left lobe is the Jekyll of the intellect, the right, on occasion at least, is apt to play the part of Hyde.

Immigration's Menace to the National Health.

An article with this title is contributed to the July *North American Review* by Mr. T. V. Powderly, Commissioner-General of Immigration The aliens, says Mr. Powderly, who give the immigration authorities the most trouble are those who come "suffering from a loathsome or a dangerous contagious disease," and of these, persons afflicted with favus and trachoma are the most numerous. Until recently the people of the United States were not familiar with either favus or trachoma; and until the tide of immigration swelled up and began to flow in on us from the countries of Southern Europe and the Orient, these diseases were not very prevalent.

While the law expressly prohibited persons suffering from such diseases from landing, it was also held that, until an alien had been examined, pronounced entitled to admission, and actually passed inward to this land of liberty, he was constructively on shipboard, and, as a consequence, not landed. The hospitals in and around New York City were not long since crowded with sick and disabled immigrants during the months of August and September, as a result of the burning of the Ellis Island Immigrant Station and hospital in the previous June. Examining the reports sent in from these hospitals, Mr. Powderly noticed that a great number were held to be treated for favus and trachoma, and for the first time he learned what these diseases actually were.

It was then decided by the Commissioner-General of Immigration to prevent, as far as possible, not only the landing of diseased aliens, but their embarkation at foreign seaports, with the intention of landing in this country, and stringent regulations were put into force to bring about these results. The agents of the steamship lines in Europe and Asia were notified that they should not sell tickets to persons suffering with either favus or trachoma, and the traffic in diseased immigrants fell off to a large extent. Nevertheless, under one subterfuge or other, or through influence exerted for sentimental reasons, a considerable number of persons, who, though suffering from infectious disease, have no right to be allowed ingress to this country, continue to gain access, to the consequent menace of the inhabitants at large, and especially to those of New York.

The Commissioner-General is certainly well advised to prevent by every means in his power those afflicted with favus, trachoma, or any other infectious malady from taking passage for this country. He aptly says that, because America is regarded as the asylum of the world, there is no reason that it should also be looked upon as the hospital.

The type of immigrant has materially altered within the past thirty years—no longer do the sturdy, clean-blooded inhabitants of Germany, the British Isles and other northern countries come in shoals to these shores. In their stead a crowd of Southern Europeans and Orientals, accustomed to living in dirt and insanitary surroundings, and often the victims of pestilential infectious complaints, herd to America, and, indeed, are a distinct menace to the national health. Every individual suffering from a disease which may be likely to infect the community should be excluded.

CHEMICAL PRESERVATIVES IN FOOD.

A writer in the *National Druggist* of St. Louis discusses the question of the harmfulness of chemical preservatives in food. A portion of this article which is of much interest to the medical profession is copied by the *Literary Digest* of July 12. It is contended that common salt and other preservatives with which we are familiar are harmful in large quantities, and that, in fact, the innocuousness of a preservative is a matter of quantity. The writer goes on to say, "Apparently, most of these journals—which have been discussing the subject—do not include sodium choride among chemicals, or imagine that there can possibly be any question as to its absolute harmlessness." Those acquainted with chemistry, however, can see no reason why $NaCl$ is any less a chemical than H_3BO_3 or $Na_2B_4O_7 10H_2O$; yet such is the force of habit, that when common salt is spoken of as a preservative of food, to nine men out of ten the idea of its true nature never occurs. That it is, under certain circumstances, a poisonous substance, and that its prolonged use may cause the most horrible sufferings and death, is also apparently forgotten, even by those who read in the daily papers of the ravages of scurvy on board whaling and other vessels short of fresh food.

Admitting that education on these points is extremely desirable, the *National Druggist* editorial is, however, not by any means in favor of leaving the investigation to the experts of the Department of Agriculture, holding that the question of food preservatives is one in which the whole world is vitally interested, and should be settled by an international commission of scientific men, appointed by the leading nations of the world.

There should not be allowed on this commission any man who is, in any manner, connected with the manufacture or sale of preservatives, or who has ever announced an opinion, as an expert, of the virtues or demerits of any substance that may be brought before the commission. If such a plan were found feasible it certainly would tend to enlighten the general public as to the use and abuse of food preservatives. The authorities would be performing a public service by taking steps to thoroughly ventilate the matter.

STATISTICS OF CREMATION.

Sir Henry Thompson, who has been for long a staunch advocate of cremation, and who has written some most able articles in support of the practice, contributes to the *Lancet* of July 5 some statistics bearing on the matter.

It appears from these figures that Germany possesses seven crematories. The total number of cremations performed at each during the year 1901 being 693. A petition signed by over 3,000 medical men has been presented in the Reichstag within the past few months with a view of rendering compulsory the cremation of persons who have died from infectious diseases.

England possesses seven crematories, in which during the year 1901 445 persons were cremated. Italy possesses twenty-two crematories, but statistics as to the number of persons upon whom cremation was performed in 1901 are lacking in some of these. There are three crematories in Switzerland, at one of which 127 cremations were performed in 1901. Sweden possesses two and Denmark one. In Austria-Hungary societies for the promotion of cremation continue to be formed under the influence of the Vienna Society. "Die Flamme" and branches exist in many towns, but the practice of cremation has not yet been legalized.

In Madrid the right of cremation has been conferred by a royal decree, while even in Russia, in spite of the protestations of the Procurator of the Holy Synod, the government proposes to issue a decree in favor of making cremation optional. In France a large crematorium is situated in the far-famed cemetery of Paris, Père la Chaise, in which since its opening, 2,299 bodies have been cremated.

In the United States are twenty-six crematories, twenty-four of which are in operation. A larger number of persons are cremated yearly in this country than in any other. In Canada, notwithstanding the opposition of the Roman Catholic clergy, the Legislature of Quebec has declared the legality of cremation, and a crematorium has just been built at Montreal.

It will thus be gathered that cremation is upon the increase in all civilized countries. The practice is in the interests of public health and sanitation, and will gain in popularity as its merits are more widely understood.

News of the Week.

Cholera.—There has recently been an increase in the number of cholera cases in the various parts of the world where it now prevails. In Manila, where it had been gradually diminishing and hopes were entertained that the outbreak was at an end, the number of cases suddenly increased to seventy-eight on July 24, the largest since the outbreak. It was feared that the city water was infected, but an analysis showed that it was not polluted. The removal of the quarantine on fruits and vegetables, which had recently been effected, possibly accounted for the renewed outbreak. In Cairo and at Moucha, near Assioot, there is an epidemic of virulent character now prevailing. In the ten days of July 15-24, inclusive, there were 307 cases with 227 deaths. There were 18 new cases in Cairo on July 25, 20 new cases on the following day, and 35 on July 28. Many of the natives die in the streets. The drinking-fountains have been shut off and other sanitary measures are being instituted. The disease also prevails extensively in Manchuria, and it is announced officially that cholera is raging at Mukden, in that province. There were 757 cases between July 3 and 14, and 81 Russians and 363 Chinese died from the disease. Between July 15 and 23 the deaths numbered 106 Russians and 276 Chinese.

A Physician Sues for Services.—Dr. John R. C. Thompson of Bridgeton, N. J., has brought suit against the township of Downe, Cumberland Co., for $2,000 for professional services in connection with an outbreak of smallpox. The claim is resisted on the ground that the contract was made on Sunday.

The American Electro-Therapeutic Association.—The annual meeting of this association will be held at the hotel Kaaterskill, Catskill Mountains, N. Y., on September 2, 3, and 4, 1902. Full particulars regarding the meeting can be obtained by writing to Dr. Robert Newman, 101 West Eightieth street, Chairman of Executive Council, or Dr. William Stevens, 70 West Fifty-second street, New York, Secretary Committee of Arrangements.

An Ohio Physician Imprisoned in Nicaragua.—Dr. Russell Wilson, a physician of Milan, O., is in a Nicaraguan prison charged with taking up arms against that government, and his friends are making every effort to obtain his release. The State Department has telegraphed the United States Consul at San Juan Del Norte (Bluefields) to care for the interests of Dr. Wilson and to send a full report about his case. Dr. Wilson was one of a party of Nicaraguan insurgents landed near Bluefields. A storm prevented the landing of the entire number and those who went on shore were captured. Dr. Wilson was taken to Bluefields, where he was tried by a court-martial, and condemned to death, but the President of Nicaragua commuted his sentence as a mark of courtesy to the United States. His case was made worse by the belief of the Nicaraguan Government that he participated in a former filibustering expedition in 1899. This, however, is disproved by the fact that he was a student in the Medical Department of the Ohio University in that year and was not graduated until 1900.

A Medical Flyer.—A physician of Winchester, Tenn., Dr. E. L. Drake, is reported to be the inventor of a flying machine which will cleave the air at a speed of over two hundred miles an hour. A number of Chicago capitalists are said to have formed a corporation with a large capital to finance the invention and build a machine to compete in the aerial races at the St. Louis Exposition.

The Health Department of Manila.—Colonel Maus, who has had a long term of service as chief of the Department of Health of the Philippines, has been relieved and ordered to Washington. He will be succeeded by Major Carter, an experienced sanitarian.

Dr. George H. Simmons.—We are very glad to learn that Dr. Simmons, Secretary of the American Medical Association and editor of the *Journal* of the same, who was operated upon recently for gallstones, is making a good recovery. Dr. Simmons had not been in good health for some time previous to the operation.

Consolidation of Medical Societies in Detroit.—A consolidation has been effected of the Wayne County (Mich.) Medical Society and the Detroit Medical Society.

McKinley's Surgeons to Be Paid.—Secretary Cortelyou, at the request of President Roosevelt, has taken charge of the settlement of the surgeons' bills and other expenses incidental to the assassination of President McKinley last September. A lump appropriation of $45,000 to meet all claims was made by Congress, and it has been arranged that Mr. Cortelyou is to make requisitions upon the Treasury for the several amounts, and that these requisitions shall be honored without delay in the Auditor's office.

A Bill for Medical Services Reduced.—By a decision of the Orphan's Court of Allegheny County, Pa., the claim of Dr. Wm. C. Browning of $340,000 against the estate of the late Senator Christopher Magee was recently reduced to $25,239.25. Of the total amount the sum of $190,000 was for professional services rendered and one of $150,000 for profits accruing from certain transactions in stock which he had failed to receive.

The Automaniac.—The editor of *The Horseless Age* felicitously suggests the word "automaniac" to designate "the new terrors of our streets, those speed-crazed paranoiacs who are now doing so much to bring the automobile into disrepute." Various and many epithets, most of them in the language of the street, and nearly all unprintable, have been bestowed upon these wretches, but a new and distinctive term would, as our contemporary well says, be desirable.

The Physicians of the Queen of Holland.—The physicians who attended Queen Wilhelmina in her late illness have been receiving honors at her hands. Prof. Rosenstein has been promoted to be a commander of the Order of the Lion of the Netherlands, and Prof. Kouwer and Drs. Roessingh and Pot have been appointed knights of the same order.

Obituary Notes.—Dr. JOSEPH BIDDLE WILKINSON of New Orleans died in that city on July 21, at the age of eighty-five years. He was for many years before his retirement one of the leading physicians of Louisiana, and was also prominent politically, serving many successive terms in the State Legislature.

Dr. CARLO DE'R. IMPERATORI of this city died suddenly on July 24, at the age of seventy years. He was born in Venice in 1832, and studied in Paris under Claude Bernard and Majendie. In 1859 he came to New York. Later he took a course in medicine at the Bellevue Medical College, from which he was graduated in 1874. Since that time he had practised on the east side. Dr. Imperatori was a member of the Greater New York Medical Association, the New York County Medical Association, the New York State Medical Association, and the American Medical Association. He is survived by a widow and two sons, one of whom is also a physician.

Dr. **Charles D. Martin** died at his home in Allentown, Pa., on July 15, at the age of fifty-five years. He was a graduate of the Bellevue Hospital Medical College in this city in the class of 1867.

Dr. **Washington Righter** of Philadelphia died of apoplexy at Atlantic City, N. J., on July 16. He was born at Lancaster in 1845, received his preliminary education at Philips Academy, Andover, and at Princeton College, and he was graduated from Jefferson Medical College in 1866. He never took up the practice of his profession, but he entered into partnership with his father in the wholesale lumber business at Columbia. He removed to Philadelphia in 1886.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE KING'S CONVALESCENCE—FÊTES—HOSPITAL BAZAARS, ETC.—MR. CHAMBERLAIN'S WOUND—FIRE IN A HOSPITAL—IMPERIAL VACCINATION LEAGUE—DEATH OF DR. CURNOW.

London, July 18, 1902.

"Out of danger"—that was the announcement for which the public were anxiously waiting when I last wrote, and that was the bulletin issued by the King's surgeons on Saturday. By a happy coincidence this announcement appeared on the morning that the King's dinner to half a million poor Londoners was given; for the dinner was one of the celebrations not postponed by his Majesty's illness. In the several localities the enthusiasm was unbounded when members of the Royal family arrived with the latest news and a message from the King hoping they were having a happy time. People of all ranks took part in the preparations and in waiting on the King's guests, and the success of the entertainment was a triumph of organization.

From that day onward the progress of the King has been uninterrupted, and the bulletins have daily declared that his Majesty's condition continues satisfactory. Consequently various forms of thanksgiving for this rapid recovery have been duly celebrated and many anticipations of the coronation indulged in. It is known that the King desires that the ceremony may take place as early as possible, and it is now understood that, provided no drawback interferes, it will take place on August 9, and the Houses of Parliament will rise on the day preceding. Meantime there is the period of convalescence, during which you will recognize the need of care, though the public with the reaction from anxiety, have been talking most of the week of the certain cure. Of course, at present, he is an invalid and must be treated as such, but his surgeons have no difficulty, as he implicitly follows their advice. The recumbent position is irksome but patiently endured, and the simple diet enjoyed. His Majesty has good nights without narcotics, and his constitution is believed to be sound. Some of the sensational journals take delight in circulating sensational false statements on this point. I repeat, therefore, that his Majesty's advisers have never detected any sign of malignant disease, and the circulation of reports to the contrary is a disgrace to those newspapers which spread them.

The wound is still dressed with gauze, granulation is going on well, and the Royal Yacht is being made ready in the expectation that early next week his Majesty may be conveyed in an ambulance to the sea and complete his convalescence during a short voyage, for the sea has always agreed with him. Among the festivities postponed with the coronation, but now going on, I may mention as interesting and unique, though not medical, the Queen's tea to 10,000 maids-of-all-work. The girls are being entertained on different days, in various places, and the number will soon be completed. Each batch of "guests of the Queen" has received a special message from her Majesty and replied with hearty wishes for the King's speedy and complete recovery. The arrangements were carried out without a hitch by the societies which take special interest in servants. Another well-managed feast was that of 12,000 school children in Kensington gardens. This was a fairly large entertainment, but yesterday 30,000 children were regaled in another park.

A successful fête on behalf of St. George's Hospital was held last week in the Royal Botanic Gardens. The entertainment included a *haka* or war dance by a number of Maori warriors, now in London, with the New Zealand premier and his family looking on. Chiefs of high degree took part in this performance, which concluded with a "chant of joy," composed for them to sing at the sight of the great white King for whose intended coronation they had come to England.

Yesterday the same gardens were the scene of the most brilliant spectacle of the season—the opening by H. M. the Queen of the great coronation bazaar on behalf of the hospital for sick children. The Queen was accompanied by many royalties, both British and foreign, and the crowd of spectators was probably greater than any similar assembly. The only one to be compared with this is the National bazaar of 1900, and that is pronounced to be the lesser function by some who were present at both. The Queen visited the several stalls and made purchases at all. At the first a cheque was presented to her Majesty for £1,000 to endow a cot to be called after herself. Accompanying this precious bit of paper, which was enclosed in a beautiful silver case, with an inscription in enameled letters, was a silver model of the intended cot. Other models were on the stall and sold freely. At the American stall the Queen bought President Roosevelt's last book, Charles Dana Gibson's sketches, and other works of art. The children's hospital will greatly benefit, and some hope is felt that its debt may be defrayed.

The Prince and Princess of Wales opened the new nurses' home at Guy's Hospital on Monday. This home is a memorial to the late Mrs. Henriette Raphael, her husband having given £20,000 for that purpose. He did not survive to see the splendid result of his munificence, but his son was present on this occasion, and the family retain the deepest interest in the memorial. The £20,000 was not enough to complete it in the style that Guy's authorities or the architects determined upon, and it is said that nearly £70,000 has been expended. The amount seems suggestive of extravagance, and will increase the misgivings of those who complain that the managers of our great charities seem always to be spending money in bricks and mortar.

The cable will have told you of the nasty cab accident sustained by Mr. Chamberlain, the Colonial Secretary, on Monday. The wound is on the upper part of the forehead, about 1$\frac{3}{4}$ inches long, and extends to the bone, which is grazed along the whole length, but there is no fracture. Three or four small vessels were ligatured and five stitches used. The wound was cleansed with sterilized water and dressed with cyanide wool. The Right Honorable gentleman was kept in the hospital until Wednesday as a matter of precaution, but no cerebral symptoms appeared. His pulse, usually slow, intermitted a little, at first, from shock and hemorrhage, but soon became steady, and no fever or inflammation has occurred. The wound is healing well.

There was an alarming outbreak of fire at the London hospital last Friday. Not much damage was done, but the occurrence points to the necessity of every precaution being taken at hospitals, as to which many misgivings have lately found expression. In this case appliances are being fitted for the supply of filtered air to the operating theatres. The great sheets of cotton wool used as fillers took fire and enormous quantities of smoke passed through the pipes. So dense were the fumes in the corridors that men could not stand upright, but some crawled along on hands and knees with hose and quickly extinguished the fire. The engine arrived in four minutes, but the amateur firemen had rendered it unnecessary.

The Imperial Vaccination League was formally established on the 30th ult. The Duke of Fyfe has accepted the presidency and Lord Avebury the treasuryship. There are several vice-presidents, the primate being one. The provisional committee includes several well-known doctors. The new organization will circulate literature and promote lecturing, meetings, and all methods of making known the truth about vaccination, and so neutralize the pernicious agitation of the antis. The Jenner society, which has done excellent work in this direction, is not to be superseded, but will continue its valuable efforts; its provincial position is a disadvantage, and the new league will, therefore, co-operate with it, and act in a wider sphere as well. Opinions will be collected as to what changes in the law are desirable, so that when amendments to the acts are proposed the league may be able to influence the government. Such questions as revaccination at school age, the transfer of the duties of the Poor Law under the acts to the sanitary authorities, the establishment of laboratories, and the supply of lymph will have early attention, and it may be hoped that the league may do much to enlist public opinion on the side of science and common sense.

Professor J. Curnow of King's College died on the 5th inst. from acute pneumonia. He was in his fifty-seventh year and had been connected with King's throughout his career, which has been exceptionally brilliant. A memorial service was held in the chapel of the college on Wednesday, and the funeral followed on the same day at Highgate. From 1873 to 1897 he occupied the chair of anatomy at King's. In 1874 he was elected on the staff of the hospital and became full physician in 1890. For a considerable time Dr. Curnow was Dean of the Medical Faculty, and he also held other appointments, in all of which he secured the esteem of his colleagues, students, and others.

THE SO-CALLED CARGILE MEMBRANE.

To the Editor of the Medical Record:

Sir: In the Medical Record of May 17 I find a very interesting article by Dr. R. T. Morris, entitled "A Report of Experiments Made with Cargile Membrane for the Purpose of Determining Its Value in Preventing the Formation of Peritoneal Adhesions." I take the liberty to enclose a reprint from the *Journal of the American Medical Association* of August 11, 1894, which I hope will establish, beyond question, my right to priority concerning the preparation and the use of the animal peritoneum for the prevention of adhesions in abdominal sections. Since 1893 I have been using this animal membrane in all laparotomies where adhesions were to be feared, with such success that I think the value of this method is completely established. It has never entered my mind, of course, that Dr. Charles H. Cargile of Bentonville, Ark., knew of my article and of my work and experience with this animal membrane previous to his own experiments. I am writing these lines only to protest against calling the method "Cargile." I can give a report of a large number of cases in which I have been using my prepared animal peritoneum to prevent adhesions in abdominal sections. Do I ask too much if I request you to give these lines a modest place in the Medical Record. Thanking you in advance for your kind courtesy, I remain,

Yours respectfully,

F. Baum, M.D.

Rome, July 9, 1902, No. 14 Via Quattro Fontane.

THE UNITED STATES PUBLIC HEALTH AND MARINE HOSPITAL SERVICE BILL.

To the Editor of the Medical Record:

Sir: I read in the Medical Record of June 12, 1902, on page 61, regarding the U. S. Public Health and Marine Hospital Service Bill: "The object of the Bill, it was explained during the closing debate, was to enable the Federal Government to take charge of the quarantine service of the country, in compliance with a growing public demand. Heretofore it had been rendered impossible of achievement because of the lack of co-operation between the Health Officers of the States and the Nation."

This statement of one of the speakers on the bill is not correct. Kindly permit me to set the matter right before the many readers of the Medical Record.

There is not a word relating to quarantine in the bill; on the contrary one of the strong arguments brought up in favor of it was that it respected the quarantine powers of each State. The salient feature of the bill, as regards State Health Officials, is Section 7, which reads as follows:

"Section 7.—That when in the opinion of the Surgeon-General of the Public Health and Marine Hospital Service of the United States the interests of the public health would be promoted by a conference of said service with State or Territorial Boards of Health, Quarantine Authorities, or State Health Officers, the District of Columbia included, he may invite as many of said health and quarantine authorities as he deems necessary or proper to send delegates, not more than one from each State or Territory and District of Columbia, to said conference.

"*Provided*, That an annual conference of the health authorities of all the States and Territories and District of Columbia shall be called, each of said States, Territories, and the District of Columbia to be entitled to one delegate.

And *provided further*, That it shall be the duty of the said Surgeon-General to call a conference upon the application of not less than five States or Territorial Boards of Health, Quarantine Authorities, or State Health Officers, each of said Boards or Quarantine Authorities joining in such request to be represented by one delegate."

It is not provided that the expenses of the delegates to these conferences shall be borne by the United States. It is not intended that they shall be junkets, but that they shall be attended by those who have at heart the health interest of their people and shall represent people who are willing to bear the expense of such service.

The Senate Committee in reporting favorably upon the Bill said: "The Committee has been impressed with the conviction that in the general public interest some recognition by Federal legislation of the State Health Authorities, in the way of consultation upon subjects of vital consequence to the localities, and as to the rules to be put in operation by both State and Federal Authorities in accomplishing the same end, would of necessity bring about better understanding, and a co-operation which would inevitably promote a fuller accomplishment of the great purpose desired by both the Federal and State Authorities. The Federal jurisdiction is exercised primarily in the interest of commerce. The local or State jurisdiction is exercised primarily for the protection of life and health in the communities, and, secondarily, in the interest of commerce. In the hope and belief that good results will come from it the Committee has inserted Section 7, above set forth."

To my mind this co-operation of the State and Federal health authorities, replacing the feeling of antagonism existing heretofore, marks one of the most important eras in the evolution of health matters in our country. Much of its future development, however, will depend upon the wisdom and spirit and diplomacy of the Surgeons-General, present and future, of the United States Public Health and Marine Hospital Service.

It is the first time that State health officials have ever received any recognition whatever from the Federal health authorities, and this was due mostly to a conference of State health officials held in Washington City, upon the invitation of the writer, on March 13, 1902, and to Senator Spooner, who instilled the spirit of the proposed "Spooner Bill" into the United States Public Health and Marine Hospital Service Bill.

Respectfully,

Edmond Souchon, M.D.,

President Louisiana State Board of Health.

Progress of Medical Science.

Boston Medical and Surgical Journal, July 24, 1902.

Operation for Cancer of the Uterus.—Edward Reynolds says in regard to the choice between the abdominal and the vaginal route, that the former is the easier, neater, more complete, and more satisfactory procedure It affords the opportunity of making an exact diagnosis of the extent of the disease at the beginning of the operation. The dangers of hemorrhage and subsequent infection are less than in the vaginal operation. It is not so likely to be followed by painful adhesions. The subjects of malignant disease, even in its early stages, stand operation badly however, and the majority of deaths are the result of shock. Vaginal hysterectomy is attended by almost no shock, and should therefore be the operation of choice in enfeebled women.

Cancer of the Uterus.—W. M. Conant states that in cases of so-called inoperable cancer four possible results may be obtained from a radical operation: (1) A cure. This is rare, but with improved methods there will probably be better statistics, and we are justified in advising a panhysterectomy; (2) Relief from present sufferings from hemorrhages, from foul vaginal discharge, impossible to live in the same room or house with the patient; (3) A condition that in some respects is worse, because the disease seems to spread more rapidly after operation; but because it is removed from the vagina there is not the danger of hemorrhage or of foul discharge, so that although the disease may be more active, it is not, all things considered, so distressing; (4) Death.

The Present Status of the Operative Treatment of Cancer of the Uterus.—W. L. Burrage concludes that absolute cure of cancer of the uterus is rare. By the best methods of operating thus far produced, only 5 to 10 per cent. of cases are well five years after operation, and a smaller proportion ten years after. The results in the case of cancer of the body are much more favorable than those for cancer of the cervix. All cases of uterine cancer, except those advanced ones which have developed vesicovaginal or rectovaginal fistula, should be operated on to prolong life and relieve suffering. The abdominal operation of Werder is the best in the early days of cancer where the disease has not gone outside the uterus and the patient is in good condition. In advanced cases and in very stout persons, vaginal hysterectomy or curetting and cautery are to be chosen.

Remarks on Cancer of the Uterus.—Maurice H. Richardson says that permanent relief by extirpation of the uterus may reasonably be expected when the disease is confined to the uterus. The removal of a malignant growth is not advisable when a cure is not reasonably to be expected. The extirpation of the carcinomatous non-prolapsed uterus is to be considered as one of the duties of the surgeon. The author is in favor of vaginal hysterectomy when the uterus is movable, when the disease is distinctly confined to the cervix, and when the vagina is capacious. When the disease is confined to the fundus he prefers abdominal hysterectomy. When it is necessary to dissect carefully the cervix and the vaginal mucous membrane, and to excise with the cervix a broad margin of vagina, and when the uterus is more or less fixed and the vagina small, he performs the combined vaginal and abdominal operation. The cervix is first thoroughly freed from below as far as the peritoneum, and the operation is completed from above. If, at the end of three years after the operation there is no evidence of recurrence, a permanent cure seems probable. If at the end of five years there is no recurrence, the disease may be looked upon as permanently cured.

Journal of the American Medical Association, July 26, 1902.

Pruritus Ani.—A. J. Byerly refers to a recent article by Edmund Andrews advocating the use of strong heat in the treatment of pruritus ani, and takes exception to some of the latter's conclusions. Andrews referred to the common practice of treating chilblains by holding the affected part before as intense dry heat as can comfortably be borne, but Byerly states that the strong heat makes the treatment disagreeable, and the chilblain is left tender and sensitive. He has therefore modified this domestic custom and immerses the chilblains in water of a temperature of 105 to 110°F. for about ten minutes (until the itching is subdued), and the result has been a treatment entirely agreeable, and one which removes the pruritus and soreness from the chilblain. Two applications usually effect a cure, but in chilblains of the feet, tight stiff leather boots must be avoided. Now, if a milder heat is more effective in chilblains than strong heat, will not a milder heat properly applied for a longer period of time prove more effective in the treatment of pruritus ani than strong heat? That is, will not water at a temperature of 105 to 110° F. properly applied for about ten minutes (until the pruritus ani is subdued) be more effective in the permanent cure of pruritus ani than water at a temperature of 130 °F.?

Medical News, July 26, 1902.

Tobacco Heart.—Frank D. Maine describes the pneumogastric as the longest nerve coming from the base of the brain, which supplies, by means of its branches, the motive power for the functional activity of the lungs, heart, and digestive apparatus. Tobacco injures this nerve throughout its ramifications, causing relaxation and more or less complete paralysis of the involuntary muscles of these organs, in proportion to the extent of its use. The characteristcs of the tobacco heart are irregularity of the heart's pulsations, rapidity of its strokes, nervous palpitation, waste of vital force, and irritability. Hypertrophy, or thickening of the left ventricle is produced by the prolonged use of this weed. Even the whole heart may be enlarged. The treatment is in general negative—that is, total abstinence. Complete recovery may occur, and hypertrophy may even disappear after the continued disuse of tobacco. The laws of hygiene should be observed, and strychnine may be prescribed.

A Few Notes on Syphilitic Bubo.—A. Ravogli states that the lymphatic glands are affected by the syphilitic virus constantly, and their engorgement is not due to the presence of the secondary eruption or to the abraded patches, as they are enlarged without these manifestations. The glands are enlarged before any eruption has yet appeared. The process affecting the glands is an irritative one, and in consequence hyperæmia and swelling are the necessary results. The swelling is caused by an increased flow of serum from the blood vessels. The pathological alterations differ from those of suppurating adenitis of chancroidal origin and also from those of syphilitic gumma. The syphilitic bubo is not a genuine inflammatory process of the inguinal gland, but is produced by the same infiltrating process which is characterstic of syphilis. It is a process especially affecting the vascular system, with an enlargement and thickening of its tunics. The lymphatic vessels are also implicated. The lymphatics are the channels best adapted for the passage of the syphilitic germs. In the treatment of syphilitic bubo, the writer speaks of the removal of the infiltrated glands. There is no necessity for antiphlogistic treatment. Mercurial applications are of great benefit.

American Medicine, July 26, 1902.

A Rare Form of Skin Disease.—Donald Parker reports this case. The patient was a little girl aged two and one-half years. The personal and family history were negative. The writer sums up the most noticeable features of the case as follows: Low fever until the last two days (the illness lasted for eight days), and even then a cool, moist skin. Rash limited to the hands and feet and lumbar region, no spots occurring elsewhere. The rash ran the course of macule, vesicle, scale, and pustule in the order named. The tongue was not swollen, but very red, as was also the throat. The mouth was blanched and cankered; there was no sign of strawberry appearance. The hands were rubbed upon each other and held in the mouth if she was not watched. There was no cough or other signs of cold at any time and the face and body were not flushed. The kidneys seemed normal. No urine could be obtained for examination. There had been no exposure to measles or scarlet fever for six months. The house was in good sanitary condition. The writer states that the diagnosis of this case is an open question.

Lobar Pneumonia in Infants.—William Fitch Cheney declares that the physical signs of lobar pneumonia in infants are often indefinite and misleading. This is especially so at the onset. Auscultation should always be relied upon more than any other method of investigation. In the first stage, the breath sounds over the congested area are distant and feeble as compared with the normal side. The quality of the sounds is often harsh, tubular, and bronchial; this is frequently the feature that first attracts attention, but it is more apt to be found after the first twenty-four or forty-eight hours. The diagnostic point is the prolongation of expiration until it equals or exceeds inspiration. This distinguishes the diseased area, even though its intensity of sound is decreased. Probably the most important point of all is the discovery of adventitious sounds. Clicking, crackling râles at the end of inspiration should always be looked for. This sign clinches the diagnosis and is often present quite early. The prognosis is almost invariably good. The treatment is simple, for the disease is self-limited. The main object is to maintain the strength.

Reconstruction of Finger-Tips by Sponge Eduction.—George E. Abbott says no method will so quickly change an abscess cavity, or an ulcer, or any part that has been curetted because of a depraved base, into a healthy granulating surface, as the sponge graft or sponge eduction method. By it, lost surfaces and lost finger-tips may be restored to the extent of half an inch or more. The essentials of a sponge graft are a fine-grained, stiff sponge. The sections must be cut transversely to the pores of the sponge. This may be done with the scissors, or with a carving knife. The sections should be one-eighth, one-sixteenth, or one-thirty-second-inch thick, and should be thoroughly sterilized. After they are applied they should be kept wet with sterilized salt solution. Eduction sponges or mastoid portions for filling cavities must be cut transversely to the tubes of the sponge, so that the granulations may grow up into them by capillary attraction, as it were. The outer side of the sponge is placed against the granulating base and sides of the cavity. These must be removed every few days, or they may be held so closely by the new granulations as to be removed with difficulty, while at the same time their removal tears the new-formed tissue. The writer has had excellent success in the treatment of injured finger-tips with this method. The sponge graft is placed in close contact with the denuded end of the finger, and is held in place with adhesive plaster and bandaged with gauze. The sponge is syringed out every day with pyrozone and boric-acid solution. A glass dropper is used as a syringe. The sponge is renewed every three days.

New York Medical Journal, July 26, 1902.

Excision of the Knee for Vicious Deformity and Tuberculous Disease in the Adult.—The clinical histories of three cases are given in detail by V. P. Gibney. He contends that excision is a remedy which may be employed in certain stages of disease, in which fixation and protection apparatus are regarded as all-sufficient, but at the same time he insists upon its insufficiency as a means of relief in the growing bones of young children. He notes that works on surgery usually recommend excision for a badly suppurating knee, but it is still the custom among surgeons to advise against excision in that obscure class of tuberculous knees in adults not attended by suppuration. The general impression prevails among surgeons that prolonged fixation in plaster of paris or any immobilizing apparatus is conducive to ankylosis, and that an ankylosed knee is just about as good as one that is synostosed. His own experience contradicts this flatly. He is personally familiar with a number of cases in which a partial ankylosis, or even an ankylosis almost complete, has proved very annoying to the patients. A number of falls and sprains have made them excessively timid, and they will become devotedly attached to a posterior splint, bound securely by a roller bandage, and will insist upon wearing this throughout life. On the other hand, when good bony union has been secured by operation, they have no fear of disturbing this union, they are relieved of the use of appliances, and they wonder why they were so long opposed to the operation.

Spinal Cord Conditions in Severe Anæmias.—Archibald Church says that while nutritional defects due to anæmia showing themselves in syncopes, mental disturbance, insomnia, and even hemorrhages into the brain and retina as well as into the spinal cord, have been well established as clinical possibilities for a long period of time, but degenerative processes secondary to or associated with anæmias have been recognized only in very recent years. While at first it was contended that these changes were largely confined to the posterior half of the cord, sparing the gray matter, it was afterward asserted that the gray matter was equally likely to suffer. Examination of a large number of reports will confirm to the unprejudiced investigator that the changes in the cord are, in a sense, mechanically located. That is, those portions of the cord which are less well supplied with blood are the first to suffer. Owing to the arrangements of the blood vessels supplying the anterior portions of the cord, especially the anterior horns of gray matter, this portion of a cross section shows comparatively few pathological changes in these cases, while the posterior half of the cord, embracing the sensory and the motor-conducting tracts, being less vascular, supplied as it is by a number of small terminal arteries, in the lowered circulatory conditions of the anæmias, undergoes nutritional reduction and consequent retrograde changes. These show themselves in sclerotic conditions. In cases of long duration and extreme degree, the other portion of the cord, including the anterior horns of gray matter, are involved with corresponding functional disturbance and physical signs It is also believed that in addition to the anæmia, a toxic factor furnishes a very active element. These changes occur not only in the classical pernicious anæmias, but in cachectic states of long duration, attended by toxic factors. The symptoms often suggest locomotor ataxia, spastic paraplegia, or multiple neuritis. As the posterior half of the cord is involved the case may present, clinically, the indications of locomotor ataxia, but if the lateral portions of the posterior half of the cord, including the crossed pyramidal motor tracts, are principally or primarily affected, spasticity and rigidity with weakness may give rise to the supposition that the patient primarily has myelitis or an ataxic paraplegia. In the course of these cases one is likely to encounter fluctuations in the symptoms, so that a case which at one time is spastic with rigidities, cramps in the lower extremities, and increased reflexes, later on may present a flaccid paralytic state with abolished knee-jerks and even lost control of the sphincters. Almost invariably these patients complain in a major degree of disturbance of sensation.

Philadelphia Medical Journal, July 26, 1902.

The Summer Diarrhœa of Children.—W. L. Harris concludes that summer diarrhœa is to a great extent a preventable disease, and it is our duty to do all we can to instruct the mother and nurse in the care and feeding of children. In our treatment of this disease we should always stop the milk, give a purge, and then carefully regulate the diet for a few days, even in the simplest and mildest cases, and in this way prevent many a case of the more serious forms of diarrhœa. The treatment of the first few days is the most important in all cases, and even the simplest cases should never be neglected under the delusion that it is natural for a teething child to have diarrhœa.

The Treatment of Summer Diarrhœa in Young Children.—Maurice Ostheimer, after considering the prophylaxis of the disease, states that the most important treatment is absolute withdrawal of food, no matter what the infant is taking. The child should be kept in its carriage out of doors, or if this is not possible, in the largest room in the house with the windows open. Few drugs are necessary. In case of vomiting, calomel is given. When there is no vomiting, castor oil is indicated. If frequent bowel movements persist, bismuth subnitrate with a little salol is given. During convalescence, a few drops of tincture of nux vomica will often be of service. As the health boards of the large cities continue to distribute hygienic regulations for the care of babies, the poor are gradually learning how to care for their children.

The Treatment of Acute Milk Poisoning—Summer Diarrhœa.—Thompson S. Westcott holds that the cardinal principle of prophylaxis is the use of pure cow's milk, as a basis of the infant's food. In many instances the danger of serious milk poisoning may be avoided if, at the slightest sign of disturbance of the stomach or bowels, milk is withdrawn and a good dose of castor-oil given. In those cases with a tendency to greenness and curdiness of the stools, this is well followed by small doses of calomel. As to the dietetic treatment, the first principle is to forbid cow's milk. Water is most important. Albumin water, salted or sweetened barley water, acacia water, rice water, or sometimes Vals or Vichy water may be given. Beef-juice is useful. As to drugs, castor-oil, or the oil combined with spiced syrup of rhubarb, should begin the medicinal treatment of summer diarrhœa. Following the clearing of the bowels, an intestinal irrigation with salt solution should be ordered. Stimulants are often needed in the severer cases. As to complications, much can be done to prevent the severer ones by prompt and rational treatment in the early stages of the intestinal disease.

The Treatment of the Infantile Diarrhœas of the Summer Season.—James H. McKee offers the following classification of these diarrhœas: (1) Dyspeptic; due chiefly to improper or to imperfectly-digested food. Bacteria may or may not play a part; acute intestinal indigestion; dyspeptic diarrhœa; (2) Infectious; in which bacteria of different kinds play the important rôle. Such organisms are almost invariably introduced in food, and nearly always in cow's milk. (*a*) Fermentative diarrhœa; mild gastroenteric infection; (*b*) Ileocolitis, enterocolitis, acute or chronic; (*c*) Cholera infantum. The first consideration in any form of diarrhœa is the diet. In the case of a bottle-fed baby, unless the trouble is mild dyspeptic diarrhœa, it is safer to withdraw milk. In dyspeptic diarrhœa of mild grade, the weaker milk formula or peptonized milk is advisable. In case of a milk infection, milk is withdrawn. Boiled water should be given frequently for the first twenty-four hours, but no nourishment. Barley water may then be given. If the baby will not take it a few drops of aromatic spirits of ammonia will often make it acceptable. When the diarrhœa has been caused by an excess of carbohydrates, barley water is contraindicated. Beef-juice is usually well borne. Animal broths may be given on the third day. Milk feeding should always be gradually resumed. A purge should always be given as a preliminary. Castor-oil and calomel are the best. In some cases an astringent, such as the salts of bismuth, or silver nitrate, is indicated. The writer has had good results from salol as an intestinal antiseptic. Some form of opium is indicated in certain cases. Enteroclysis and hypodermoclysis are indicated in some cases. As stimulants, when necessary, brandy, old whiskey, atropine, and strychnine, are valuable. The cold pack is valuable in the treatment of fever. The most frequent complication is catarrhal pneumonia, which is to be treated as it is when occurring under ordinary conditions.

The Lancet, July 19, 1902.

A Series of Cases of Jaundice in the Fœtus.—G. F. Smith relates the histories of five cases, all children of the same mother. Only the first-born survived; the second was still-born, and each of the remaining three lived but a few days. In none of the fatal cases was their obstruction to the flow of bile into the bowel, for the first and subsequent passages were deeply bile-stained. The mother had an attack of jaundice, while carrying the child that was still-born; otherwise her history was negative. The father was healthy and the family history on both sides was negative. The author is at a loss to account for these cases and expresses ignorance as to the cause of the jaundice, or, rather, the excessive bile secretion which in each case was present before birth and was the direct cause of death.

Six Cases of Meningitis in One House with Two Deaths.—The cases reported by E. H. Sweet all occurred within a period of two months. No autopsies were permitted. The house stood on a sandy loam and was detached. Part of the floor of one sitting-room was damp for a long time, but this matter was relieved by drainage. The brick floors of the lower rooms were laid directly on the surface of the ground without any air course and the soil was full of decaying vegetable matter. The father of the children was tuberculous and the same diathesis was present in the mother's family—she herself being not very strong, but with no definite disease. The meningitis cases presented many points of difference from the conventional descriptions of either cerebrospinal or posterior basic cases. There was no retraction of the head, irritability or photophobia squint, convulsions or screaming, except that in one of the fatal cases convulsions were present in the right arm and leg. The main symptoms of onset were violent headache, vomiting, stiffness about the neck, and constipation. Several of the adults in the house were thus attacked, but all recovered. The author attributes the infection to the house or soil, but could find nothing wrong, except as above stated.

Some Rare Cases of Sarcoma of the Thyroid.—Four cases are reported by P. L. Daniel. In this series the ages were respectively fifty-seven, fifty-nine, sixty, and sixty-nine years. The two younger patients were males, the two older were females. The patient who was sixty years of age had the symptoms of myxœdema, and the one who was aged sixty-nine years had the affected lobe extirpated. The histological varieties of sarcoma found in the thyroid were either spindel- or round-celled; in three of the following cases the cells were round and of medium size. In the fourth the structure was that of a giant-celled sarcoma. The duration of life in malignant thyroid is variable, from nine weeks to two and a half years being the limits, although in those cases grafted on to pre-existing simple growths the date of origin of maligancy is uncertain, and its duration may be considerably longer. These four cases terminated fatally in eight, nine, twelve, and seventeen months respectively, from the period of earliest observation of the growth, and, being primarily malignant, the history is fairly accurate. The immediate cause of death in each case was recorded as follows: The first patient died suddenly from heart and respiratory failure five or six hours after tracheotomy; the second from syncope on the day upon which he was prepared for tracheotomy; the third, five days after extirpation, from exhaustion; and the fourth from general suppurative peritonitis, pleurisy, and pericarditis. The clinical histories are given in full.

Injuries of Nerves.—A. A. Bowlby reviews the history of experimental nerve degeneration and regeneration. An injured nerve regenerates to a great extent, but never completely without union with the proximal end. The nerve-fibers, newly formed, undoubtedly undergo a second atrophy, if they do not join the upper end and if they are not used for a long time. If when injured nerves are united, the two ends are in close apposition, there are formed two new axis cylinders, and new permanent tissue uniting the ends, much as callus unites a fracture. If the nerve ends are more than an inch apart, no useful union ever results. The author then proceeds to study the changes in the muscles, supplied by the injured nerves—as evidenced both by inspection and by electrical reaction; also the changes in the hair, skin, and joints. As to actual suturing, the author believes that the individual fibers get very much mixed up. Hence, upon recovery, the patient may possess good tactile sensation, and yet be unable at first to distinctly localize the same. As to motor fibers, it is evident that many of them do not necessarily get properly joined at all, and the result is, that though we may talk of successful union of a nerve, it is most likely that even in the most successful cases all the sensory fibers do not get joined up, nor do all the motor fibers. As a practical result, surgically speaking, as far as patients are concerned, there is evidence that even in these successful cases there is not that complete restoration of nerve tissue which would be implied in the term "cured." The patient is not usually cured completely, for the part is often not innervated as it was before the injury.

A Case of Rheumatic Hyperpyrexia Followed by Symptoms Resembling Those of Disseminated Sclerosis.—The patient of W. Allen and J. W. Russell was a butcher, aged thirty years. He had an acute rhematism running its course in three days, but after exposure developed a very high temperature—107°-108° F.—with violent delirium. It was controlled by cold packs, but rose again next day, the thermometer register reaching its maximum, 115°. He became delirious, later unconscious with cyanosis and shallow and irregular breathing, and was apparently moribund. The pulse was good, however, and cold water vigorously applied again brought down the temperature. During the packs he had several convulsions. There was a slow return to consciousness, lasting over several days, with some intermittent and partial return of the high temperature. On his regaining consciousness it was found that he articulated with great difficulty and that he was extremely ataxic in the legs. Eight months later he was unable to walk or stand without support. With help he walked with short steps, putting each foot forward with great care and much unevenness of movement. On standing with the feet together and the eyes shut there was complete loss of balance. The coördination of the upper extremities was similarly, though to a less extent, affected. The movements of the hands and fingers were unsteady, and writing was almost impossible, the pen spluttering and catching on the paper and the attempt being given up in despair. When examined some eighteen months after the original attack, symptoms resembling in a general way those of disseminated sclerosis were present and a similar finding followed an examination two years after. Reference is made to a similar case previously reported by Foxwell. In this latter case the suggestion was made by the author that the symptoms pointed to a diffused inflammation occupying the substance of the medulla and the lower half of the pons.

British Medical Journal, July 19, 1902.

The Functions of the Epiglottis.—Knowles Renshaw concludes that the only function performed by the epiglottis during deglutition is to act as a slight lateral protection to the glottis. The main function of the epiglottis is to prevent the secretions of the upper air passages, etc., from entering the larynx when in a state of rest. By its means these secretions are deflected into the pyriform fossæ, and so find their way into the œsophagus. The influence of the epiglottis over phonation is at present undetermined and uncertain.

Acute Non-suppurative Perinephritis—David Newman divides into three classes inflammation of the cellular and adipose tissue surrounding the kidney: The lipomatous, the sclerosing, and the suppurative. In the large number of cases of perinephritis consequent to the extension of infective material from distant parts, the disease culminates in suppuration. In a few instances it does not. Great induration may take place without any suppurating foci forming. The writer describes a case in which the patient suffered from an acute pleurisy, which spontaneously recovered without going on to empyema. That an infective process extended from the cavity of the thorax to the renal tissue around the right kidney seems to be the plausible explanation of the case. For an attack of acute pleurisy which lasted for over four weeks, was followed by severe pain in the right lumbar region, unassociated with fever or any symptom of renal disease. The physical signs showed great enlargement in the right renal region. At the last examination of the patient, the renal swelling had decreased to about one-third its original size and there was no pain. There was, however, a sense of weight in the lumbar region.

Some Anomalous Cases of Tabes Dorsalis.—James Taylor divides these cases into two classes: Those in which ocular symptoms or symptoms attributable to disease of the optic nerve are the chief ones, and those characterized by various unusual conditions, such as gastric crises, joint troubles, perforating ulcer, or other trophic changes. In the first class, the most common form have either paralysis of some ocular muscle or some optic atrophy. The levator palpebrarum is most often affected. It is common to find defects in other muscles supplied by the third nerve. Ptosis, alone, is rare if unilateral. There may be paralysis of either one or both sixth nerves. Generally those ocular palsies which occur in tabes are transcient in character, and usually clear up under the influence of iodide and mercury. Sometimes they disappear when neither drug is taken. There is a class of cases in which the Argyll-Robertson pupil may be the only sign of any importance. As to the treatment of gastric crises, there is nothing which controls these except the hypodermic use of morphine. There is a class of crises in which the larynx is affected. These crises are really choking attacks. There is great distress with cyanosis. Sometimes tracheotomy has to be performed. The most striking thing about the so-called Charcot joint is the deformity of the affected joint, which is produced without any pain. In these joint cases drainage seems to be occasionally beneficial. The writer then reports several cases.

Squamous Epithelioma of the Larynx in a Man Aged Twenty-four; Thyrotomy; Excision of the Larynx.—G. Victor Miller reports this case. The patient was a locomotive engineer and suffered from difficulty of breathing. The writer, on examination discovered a large growth occupying the region of the right cord, and almost completely blocking the glottis. Tracheotomy was performed, while the patient was unconscious from impeded respiration. The onset of the trouble had begun with hoarseness. A fortnight after this first operation, thyrotomy was performed, and a large growth, springing from the right cord, was found filling the larynx. The growth was rough on the surface and firm in consistence. It was cleared out and a large abscess in the hyoid region evacuated. Examination microscopically showed the tumor to be malignant papilloma. Obstruction to breathing again developed and thyrotomy was again performed. The denuded area was cauterized. The patient would not submit to having the larynx removed till some time later, when the entire larynx with the muscles attached to it was taken out, as well as the anterior wall of the pharynx, which was extensively diseased. The epiglottis was also removed. In two months the wound was almost healed. About five weeks after this there was recurrence in the scar, apparently in the region of the external wound. The patient lost flesh and strength rapidly, and died in about six months.

Deutsche medicinische Wochenschrift, July 3, 1902.

Effect Produced by the Inoculation of Specific Substances Obtained from the Bodies of Typhoid Bacilli.—Albert Schütze, by the repeated inoculation of substances extracted from the bodies of typhoid bacilli, has produced in rabbits and guinea-pigs a specific agglutinating serum of high power. Such a serum, however, possesses no immunizing power, and it is certain that no relation exists between the agglutinines and immune bodies. This serum when mixed with one-third of the amount of the fluid employed for the inoculation and maintained at 37°C. for half an hour produces a precipitation provided that the serum is of high agglutinating power.

Presence of Specific Substances in the Bodies of Typhoid Bacilli.—L. Brieger, by a special process, has been able to obtain from the bodies of live typhoid bacilli a substance which, upon inoculation into rabbits, gives rise to a specific agglutinating serum of considerable power. No immunity is, however, produced in the animals so inoculated. Typhoid bacilli which have been submitted to this process are able, upon inoculation, to give rise to a specific agglutinating serum of low power, so that it is evident that the process does not extract from the bodies of the bacilli all of the substance which gives rise to the agglutinating serum. The extracted substance itself does not produce agglutination or hinder the growth of the typhoid bacillus. So far as these experiments go they substantiate the view that agglutinating and immunizing substansce are distinct and separate bodies.

Berliner klinische Wochenschrift, July 7, 1902.

Minimal Narcosis in Minor Surgical Operations and Reduction of Fractures.—Riedel says that in small surgical operations in which local anæsthesia is not sufficient to produce the desired result and in all cases of reduction of fractures, chloroform is much to be preferred to ether for producing general anæsthesia. In these cases the amount of chloroform necessary is from 80 to 100 drops. This amount should be administered inside of two minutes and preferably upon a fasting stomach. The patient is not under complete narcosis, but operative procedures and manipulation, if promptly begun at the expiration of the two minutes and quickly completed, cause the patient no pain. In cases in which chloroform is absolutely contraindicated ether may be used, but considerably more is necessary and a longer time is required to produce the desired result.

Paralysis of the Ulnar Nerve Following Typhoid Fever.—K. Liepelt's case developed the paralysis during convalescence from an attack of typhoid of medium severity. The involved muscles soon became atrophied and permanent deformity resulted. Six months thereafter, no electrical treatment having been used in the interim, the circumference of the affected hand was 1 cm. less than that of the sound hand. Electrical reaction was entirely absent in the muscles of the ball of the little finger, the interossei and the m. adductor pollicis. Hyperæsthesia against temperature was still present, but cutaneous sensibility to the faradic current was absent in the involved territory. No improvement has taken place, and the lesions are believed to be permanent. Including this case, literature contains twelve cases of paralysis of the ulnar nerve following typhoid. Three of these entirely recovered, three showed some improvement and the others remained permanently paralyzed. This number of cases, however, is too small to permit final conclusion with respect to prognosis.

Münchener medicinische Wochenschrift, July 8, 1902.

Widal Reaction in Weil's Disease.—Theodor Eckardt reports two cases in which the clinical symptoms corresponded accurately with those observed in Weil's disease, but in which the blood serum of the patients produced a pronounced agglutination of the typhoid bacillus. In the first case two observations were made, and in each instance a positive reaction was obtained in a 1 : 100 and a 1:1000 dilution, after one-quarter of an hour and two hours respectively. In the second case only one observation was made, the reaction being positive in a 1:100 dilution in one and one-half hours. In a 1:50 dilution a like result was obtained in three-quarters of an hour. The author regards the diagnosis of these cases as somewhat in doubt, but is inclined to consider them as types of typhoid infection accompanied by icterus and enlargement of the liver.

Finsen's Light-Treatment in Lupus, Rodent Ulcer, and Vascular Nævi.—Arnold Sack says that the primary effect of this treatment is to be observed in the walls of the blood vessels, and consists in a swelling and growth of the endothelium. This is most readily observed in simple angioma, but can also be plainly detected in lupus lesions. The favorable results produced are in no way due to a cauterizing effect of the light, as is supposed by many. This is shown by the clinical course of the case, the late appearance of the light reaction, and the entire absence of any coagulation necrosis. The retrogressive changes of a cellular character, which are observed and are of a necrobiotic nature, are purely elective in that they involve the less resistant cells of the diseased tissue, while the healthy cells of the surrounding sound tissue are stimulated to the increased activity. Histological research shows that photo-chemical properties of the light play a greater part in the results obtained than does its bactericidal power, although the latter effects are not to be entirely ignored.

Itching Eruption in Children.—F. Siebert considers those various cutaneous eruptions which occur in children and which are described by different authors under various names, as urticaria papulosa, lichen urticatus, strophulus, varicella pruriginosa, prurigo infantilis, etc. The eruption may be either macular, papular, or vesicular in character, and is usually accompanied by intense itching, although infrequently very few subjective symptoms are present. It may appear any where upon the body, limbs, or face, but is most frequently seen upon the buttocks and extensor surfaces of the extremities. It is not uncommonly observed upon the soles of the feet and external malleolar regions. Its chief clinical characteristic is that it occurs in successive crops, each crop being of two or three days' duration. The etiology is not clear, but in most instances is thought to be dependent upon a poor general condition of the patient. The diagnosis is somewhat difficult and principally rests upon the appearance of successive crops, as mentioned above. Local treatment appears to be merely palliative, and the best final results are obtained by the internal administration of ichthyol.

French Journals.

The Sphynx Facies in Myopathy.—Gilbert Ballet and Delherm report two cases of patients affected with myopathy in whom the peculiar facies was caused by enlargement of the base of the neck. This enlargement was bilateral in the first patient but unilateral in the second. The enlargement was caused by the prominence of the trapezius muscle. The neck resembled that of the Egyptian statues, particularly that of the Sphynx, the trapezius recalling the appearance of the lateral fillets which in the statues fall from the coiffure. This classic form of the neck in the myopathies the writers propose to designate as the facies of the Sphynx.—*Archives de Neurologie*, July, 1902.

Ganglionic Fever.—Grattery and Merigot de Treigny speak of the connection between ganglionic fever and infection of the nasopharynx. The infection seems most often to be due to the streptococcus and to enter the system by the way of the nasopharynx, but can also apparently be due to other microorganisms and invade the organism by another route. A form of evolution almost cyclic, with intermittent febrile manifestations, appears to be very characteristic of the disease. The ganglionic system of children seems especially sensitive to this infection, and is attacked most often through the nasopharynx. The true malady is an angina. This disease, as observed in two adults and in one child, caused insignificant manifestations in the former, but in the child it excited a very intense reaction. For the lymphatic system of a child is very active and the mucous membranes of the nasopharynx are very susceptible.—*Journal des Praticiens*, July 5, 1902.

Headache and Neuralgia of Nasal Origin.—H. Lavrand speaks of various reflex nasal neuroses, such as cough, glottic spasm, asthma, neuralgia, tic, migraine, visual troubles, vertigo, epileptic attacks, mental disturbances, exophthalmic goiter, etc., which are due to certain nasal lesions. These lesions are swelling and turgescence of the mucosa of the inferior turbinates, or, indeed, mucous polypi, foreign bodies, spurs or deviations of the septum. Some of these lesions are temporary and some are permanent. Besides these, is the existence of hyperæthesic zones. Exploration of the nose with the use of cocaine will demonstrate these. When these troubles present themselves, then, as exact a diagnosis as possible should be made and the precise part of the nose responsible for the trouble should be determined. Then treatment both special and general should be instituted, based on the diagnosis. The writer then reports cases in support of his statements.—*Journal des Sciences Médicales de Lille*, July 5, 1902.

Aneurysm of the Ascending Aorta in a Syphilitic Subject Treated by Injections of Gelatinized Serum.—Louis Spillmann declares that the efficacy of treatment of aneurysms by the use of coagulating injections has not been perfectly demonstrated. He reports the case of a man of forty-two years who presented himself for treatment with a sacculated aneurysm of the ascending aorta. He had suffered from syphilis. A swelling was noted in the right anterior thoracic region. It was very painful on pressure. The voice was rough. This dated from the appearance of the swelling. The patient suffered from vertigo and vision was feeble. The patient was emotional. He was treated with injections of gelatinized serum. Besides this he was given specific treatment. He improved so much that he was able to resume his work. At the end of twenty months he entered the hospital again with an attack of pneumonia, to which he succumbed. Autopsy demonstrated the correctness of the diagnosis that had been made. There was a large sacculated aneurysm of the aorta, the sac of which was almost obliterated. From an anatomical point of view, then, the aneurysm at the time of death was not dangerous. The case is recorded to add evidence to that already existing that medical treatment as decribed in these cases is capable of producing excellent results.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, July 6, 1902.

Annals of Surgery, July, 1902.

Bony Cysts of the Middle Turbinated Body.—Two cases are reported by G. E. Shambaugh, who reviews the conflicting views as to the pathology of this condition. He also adds the findings in another case discovered in the post-mortem room. He believes that the concha bullosa (middle turbinate) represents merely an enlarged ethmoid cell. This enlargment may be due to distention from the pressure of inflammatory products in a cell, the outlet of which has become closed, but this theory cannot, according to the author, be accepted as universal in its application. Many cases are merely anatomical variations, the result of developmental anomalies.

Traumatic Rupture of the Spleen; Splenectomy; Death on the Sixth Day.—E. A. Balloch reports the case of a colored girl, aged seventeen, who was knocked down and kicked in the left side. She was unconscious for ten minutes and was without treatment for three days. When brought to the hospital and examined a diagnosis was made of peritonitis with intraabdominal hemorrhage and probable rupture of the spleen. A cold coil was applied to the abdomen, saline purgatives given freely and enough morphine to control pain and restlessness. Operation was undertaken at the earliest practicable moment. A long laceration of the spleen was found running the entire length of the organ posteriorly. Two double handfuls of clots were turned out. There seemed to be no chance to save the spleen, so it was removed. Death ensued in six days. Autopsy showed the following conditions: Brain, vessels, and membranes normal. Thorax: beginning hepatization lower lobe of left lung. Right pleura slightly adherent. Red hepatization upper lobe right lung. Heart normal. Abdomen: wound area in good condition. No blood in abdominal cavity. Gangrenous peritonitis, involving chiefly colon and lower portion of ileum. Spleen absent. All other abdominal organs normal, except that they were soft and anæmic.

Gangrenous Intussusception in a Child Four Years Old; Intestinal Resection; Recovery.—C. N. Dowd reports the case, dwelling especially on the value of end-to-end suturing with an inner row of stitches through all the layers of the intestine and an outer row through the outer layers. His patient was a boy four years and four months old. The symptoms began with abdominal pain and discomfort continuing for ten days, during which he had no movement of the bowels, though enemata were repeatedly given. For five or six days the vomitus had the appearance of small intestinal contents. Abdominal incision revealed an intussusception about the middle of the ileum. It was about two inches and a half long. The bowel below this point was empty. On gentle manipulation, an opening appeared through the intestinal wall, which was gangrenous at the site of intussusception. The intussusception, two or three inches of intestine at each end of it, and a gangrenous piece of the mesentery were excised. A circular enterorrhaphy was then done. The first row of stitches passed through all the layers of the intestine and brought the peritoneal surfaces into close apposition at the margin. At the mesenteric border they were so placed as to obliterate the dead space there and hold broad peritoneal surfaces together, well supported by intestinal wall. A second row of Custhing stitches was then taken outside of this, and this was in certain places reinforced by a third tier of similar stitches. The intestine was then returned into the abdomen, and thorough irrigation with hot saline solution given. The abdominal incision was closed with tier sutures. Intravenous infusion of hot saline solution, one and a half pints, was given, and the patient put to bed in a fairly good condition. The bowels moved on the next morning and recovery was uneventful, excepting for a small mural abscess. The child ate ravenously, gained strength rapidly, was out of bed in four weeks, and two weeks later went home. He has continued well ever since.

Intestinal Polyposis and Carcinoma.—J. Niemack reports a case of the rare condition known as intestinal polyposis. His patient was a girl of twelve years with obscure abdominal symptoms. Rectal examination revealed large numbers of polyps, ranging in size from a pea to a walnut, the pedicle of some of them being so much thinned that they fell off with hemorrhage. At three different times about one hundred polyps were removed with the galvanic snare. The dulness and resistance of the abdomen disappeared; it became flatter; but after having removed all the tumors as high up as twelve inches, the author realized that beyond his reach there were a great many more. About this time there could be felt spread through the whole abdomen what seemed to be enlarged mesenterial glands. The urine continued normal, the bowel movement dysenteric and foul smelling, frequently containing necrotic polyps. Every treatment utterly failed and she soon died from emaciation. Post-mortem examination showed general anæmia, flabby, pale heart, mesenterial glands slightly enlarged, the mucosa of colon and several inches of lieum were more or less beset with polyps. Some of them were little nodules of pea size just standing out from the mucosa, others had pedicles up to an inch in length. The largest one, of cauliflower shape, was in the ileum. The microscopical diagnosis was "adenoma papillosum." Several months later the father of the girl began to have rectal hemorrhages. The subsequent progress of his case led to a diagnosis of adenocarcinoma and a radical operation was done. The patient made a good recovery. In reviewing the two cases the author notes that the presence of other polyps near the carcinoma suggest strongly the malignant degeneration of primary simple papilloma. The latter disease was the daughter's fatal sickness. By the patient's first examination two years ago the fact was ascertained that the father became affected with rectal polyps after his daughter's death. These facts would suggest a possible infectiousness of intestinal polyposis, and the difference of the ages would account for the malignant character by "intensity" in the father by "extensiveness" in the girl.

Motor Aphasia Due to a Small Cortical Hemorrhage in the Region of Broca's Convolution; Trephining; Recovery.—The patient of L. W. Hotchkiss was a man aged thirty-nine years who had fallen backward down stairs a distance of nine feet, striking presumably on the back of his head. He remained unconscious for eight hours. On recovery he was dazed and had great difficulty in talking, but was able to walk to the hospital. When examined no paralysis was found, but he appeared to feel weak and to be much distressed over his inability to talk. He recognized objects presented to him, and if asked if he knew what the object was, responded with "Yes," "Certainly," but could not name it. He could not speak his own name, but could write his first name, or rather the first part of it, fairly well. He could say "Yes," "Certainly," "Sure," and some other words not noted, and used these frequently and instead of the words he wanted to use. It was also noticed at this first examination that when a question was put to him he would make great efforts to answer it, as shown by the expression of his face, and after a struggle give it up without articulating a single word. The later development of right facial palsy was present, and this, with the condition of speech above described led to a diagnosis of pressure over the speech area of the cortex. Trephining revealed the dura beneath the opening black, tense, and pulseless, There was no hemorrhage outside the dura, nor any evidence of fracture of the skull in that region. The trephine hole was enlarged in a forward and downward direction, and the field occupied by the clot clearly exposed. The dura was opened by a curved incision and turned down, exposing the clot beneath. Some dark fluid blood had already been withdrawn by an aspirator-needle before opening the dura, and a little more escaped as soon as it was incised. The hemorrhage, so far as could be observed, did not come from the vessels of the dura, but from some small cerebral branches. The clot was firm and moderately adherent to the cortex of the brain, and had to be washed away with a stream of salt solution, and some of it was detached carefully with a smooth blunt instrument. Two or three small fragments of brain substance came away with the washings, and there was, perhaps, a slight cortical laceration near the anterior edge of the trephine opening, but its extent was not clearly made out. Some slight oozing of red blood occurred after removal of the clot, but soon ceased. The operation was finished in the usual manner. The patient made a complete recovery both as to health and speech restoration.

The American Journal of the Medical Sciences, July, 1902.

Fecal Impaction in Typhoid Fever, with Report of Cases.—John Norman Henry reports a number of cases of fecal impaction in typhoid fever, and calls attention to these facts; this condition is not so uncommon as the paucity of the literature on the subject would lead one to suppose. Diarrhœa may accompany impaction, and thus divert suspicion from the real state of affairs. Overdosing of milk, especially in the case of children, is an important etiological factor.

Primary Carcinoma of the Urethra in Women.—Hiram N. Vineberg states that this affection in women is very rare. Secondary involvement of the urethra by extension of the carcinomatous growth is not uncommon. This is pre-eminently a disease of middle and advanced life. The first symptom may be a burning sensation attending the act of voiding urine. Hemorrhage and discharge are very late symptoms. The conditions from which it must be differentiated are: Urethral caruncle, prolapse of a part of the urethral mucosa, and fibroid mucous polypi. The prognosis will depend upon the extent of the disease. As to treatment, total extirpation when feasible should be performed.

An Extensive Outbreak of Food Intoxication.—A. P. Ohlmacher describes this outbreak among over 200 epileptics in a hospital at Gallipolis, Ohio. The symptoms were characteristically those of food intoxication. And investigation was instituted, and suspicion finally centered on oatmeal used for a certain breakfast. The oatmeal was cooked in a steam-table. There was no provision for the escape of steam, except through doors and windows. Quantities of dust collected on the ceilings, which were dampened twice a day by steam, and thus gave favorable conditions for the growth of bacterial inhabitants of the dust. The plaster finally became loosened and was knocked down. Although the steam-table was covered at the time, the plaster dust insinuated itself everywhere, and in this way it reached the warm oatmeal. This offered a culture medium for the microorganisms, which multiplied and produced their toxic products. Laboratory experiments confirmed this conclusion.

Hypertrophy of the Lymphoid Tissue at the Base of Tongue as a Cause of Cough. Herman Jarecky calls attention to hypertrophy of the lymphoid tissue at the base of the tongue as one cause of cough. The symptoms are: Feeling of foreign body in the throat, loss or impairment of singing voice, huskiness, radiating pain in the ear and chest, tickling and feeling of fulness in the throat, dysphagia, vomiting, glottic spasm, and cough. Many patients have no undue symptoms. Effective treatment consists of removal of the tissue by means of the usual instruments or cautery. In cases in which operation is refused there may be applied a solution composed of iodine crystals, potassium iodide, glycerin, and ol. menth. pip., for the purpose of shrinking the growth. The growth can also be removed by chemical caustics, astringents, and silver nitrate fused on a probe. The after-treatment consists of antiseptic sprays, pieces of ice, cocaine spray, or lozenges in case of pain. The food should be soft.

The Clinical Association of Cancer and Tuberculosis, with Report of a Case.—G. W. McCaskey concludes: (1) Cancer and tuberculosis are so rarely associated in the same individual as to indicate a mutual antagonism between the two diseases. Autopsies on 281 cancer patients revealed only 1¼ per cent of cases of tuberculosis. In the non-cancerous its frequency is nearly twenty times as great; (2) The antagonism is not "diathetic," but is probably due to the chemical products of the two morbid processes, that of each being inimical to the other; (3) There is a rather intimate relationship existing between the two diseases in certain families. The existence of either appears to favor the occurrence of the other, probably by a lowering of "resistance power" in the individuals of such families; (4) The two diseases are not absolutely incompatible. They may very exceptionally exist in different parts of the same individual. Still, more rarely, they may exist in the same organ, and even in identically the same tissue. In the latter case it is probable that the primary disease was quiescent when the secondary one developed; (5) In view of these apparent antagonisms, and the occasional retrocession of cancer after the use of tuberculin (though very doubtfully attributable to the latter), it would seem worth while in properly selected inoperable cases of cancer to try the systematic local injection of tuberculin in the cancerous tissue.

A Case of Jacksonian Epilepsy Caused by Tumor of the Brain.—Charles W. Burr and William J. Taylor report a case of brain tumor, the first signs of which manifested themselves in an epileptic attack. These attacks were repeated from time to time. Later, he complained of headache, which came on suddenly and passed off gradually. His eyesight rapidly failed on account of the rapidly increasing choked disk in each eye. Diagnosis of brain tumor was made. Its location was more difficult to determine. There was entire absence of palsy, so the motor cortex could scarcely be the primary seat of the disease. Sensibility in all forms, and the stereognostic faculty were preserved, so the region immediately posterior to the motor area was excluded. But it seemed that the tumor must be situated near the motor cortex or the convulsions would not all have begun locally. Hence, the tumor was located for operative purposes, in the prefrontal lobe, adjacent to but not invading the motor area. At operation a large osteoplastic flap in the right parietal region over the Rolandic area was made. There was great tension, and when the dura was cut a mass of brain tissue came out in the pre-Rolandic region. This mass had no distinct outline. A large mass, about the size of a hen's egg, was removed. There was total palsy of the left side, following the operation. Surgically, the patient was well in ten days. Microscopical examination of the tissue removed at operation failed to reveal any evidence of tumor. Still the writer thinks a tumor was present, but deeply seated. This disease lasted for seven years, and it was almost six years before any other symptoms than the fits appeared. Generally cerebral disease is much more rapid. Necropsy could not be obtained. Another interesting point was muscular wasting of the palsied side, which came on acutely. The error at operation was the removal of inflammatory tissue, while the tumor was left behind. This was due to the pathological appearance of the brain by which the operators were misled.

The Journal of Tropical Medicine, July 1, 1902.

Epidemic Dysentery in Grenada During the Latter Months of the Year 1901.—A Consideration of Its Cause, Symptoms, and Treatment.—A. B. Duprey says that there were 260 cases of dysentery treated between August 7 and December 29, 1901, of which number 224 are recorded as giving positive results one way or the other; the remaining thirty-six being doubtful as to their termination. The number of cases treated with sulphur and Dover's powder was 193, with a mortality of 8.4 per cent. The immediate result of the treatment with sulphur was in all cases a stoppage of the blood and mucus; the straining was much lessened and the motions were less frequent and more fluid. The griping pains were just as severe, but subsided at once on giving morphia. The treatment of dysentery by sulphur, whether in an acute or chronic stage, deserves the highest recommendation. Ipecacuanha gave less good results, owing to constant retching and vomiting.

Yaws.—J. Numa Rat, in considering the differences between yaws and syphilis, gives the following as the most important ones: Yaws is limited to the tropics; it may be either a general or a local disease; its microorganism may exist in the soil; it is not hereditary; it is rarely contracted by sexual intercourse; it is rarely observed in infancy; it is commonly met with between the end of infancy and the tenth year of life, as many as 51 per cent. of the cases occurring during that period Only about 8 per cent. of the cases occur between the twentieth and the thirtieth year of life. Its primary lesion is a soft ulcer and never an indurated chancre; its primary lesion appears two weeks after inoculation; its secondary eruption does not show itself until about ten weeks after the appearance of the primary lesion; its secondary eruption is not symmetrical, it is monomorphous the squame, papule, and tubercle being stages in the development of the characteristic fungating growth. Its secondary eruption is characteristically fungating; its second stage is never attended by lesions of the mucous membrane of the fauces. It never produces any eye affections. It never invades the viscera or the nervous system. It attacks bones not from within but from without by extension of the inflammation excited in the neighboring cutaneous tissues It presents histopathological differences from syphilis which the writer enumerates, the chief ones beside hyperkeratosis being the absence of fibrillation in the growths of yaws, and of any intracellular hyaline degeneration or colloidal degeneration of the fibrous stroma.

Medical Graduation of Foreigners in France.—In 1897 a circular was issued by the French Minister of Education relative to the granting of medical degree of French faculties to foreigners. It was ordered that after the date of the ordinance foreigners might obtain a degree of Doctor of Medicine which should not carry with it the right to practise medicine within the territory of the French Republic. The number of such degrees granted since that time is given in a recent report as eight, a fact which shows that the purely decorative distinction offered to foreigners by the French faculties is not in great demand.—*British Medical Journal.*

Society Reports.

THE MEDICAL SOCIETY OF NEW JERSEY.

One Hundred and Thirty-sixth Annual Meeting, Held in Atlantic City, N. J., June 24, 25, and 26, 1902.

JOHN D. MCGILL, M.D., OF JERSEY CITY, PRESIDENT.

FIRST DAY—TUESDAY, JUNE 24.

THE meeting was held in the New Rudolf Hotel, Atlantic City, under the presidency of Dr. John D. McGill of Jersey City.

Honorary Membership.—Dr. J. LEONARD CORNING of New York was elected an honorary member of the society.

Report of Committee on State Sanatoria for Tuberculosis.—This committee reported that, although the bill that they drafted passed the Legislature by a large majority, it was only at the last moment, and with the greatest difficulty, that they succeeded in securing an appropriation of $50,000 to make it effective. Had it not been that the bill received the cordial support of Governor Murphy and of Mr. John G. Horner of the Legislature, even this modest appropriation would probably not have been made. It was estimated by Dr. C. J. Kipp, one of the committee, that there were at least five hundred indigent consumptives in the State, and that, in order to care for consumptives systematically throughout the State of New Jersey, the sum of $200,000 would be required. The society urged the committee to continue the good work, and endeavor to obtain a sufficient appropriation for both the erection and maintenance of a State sanatorium for tuberculosis.

The Septicæmia Clause in Accident Insurance Policies.—Dr. DANIEL J. STROCK of Camden called attention to a very general misapprehension existing among physicians regarding the true import and value of the septicæmia clause so commonly attached to accident insurance policies issued to physicians. It was well known that many physicians took out accident insurance largely because of the supposed protection that this clause gave them; hence, the speaker thought, it was but right to disabuse their minds regarding much of this so-called protection. It was true that the wording of the clause was such that one could legally claim identity under it only when the septic matter had been "introduced into the system *through any wound received by him while performing a professional operation* on a person or body of some one other than himself," but it was quite generally believed to protect the physician who becomes septic through the entrance of infective matter through any slight abrasion, such as often exists on the hand, and is unrecognized at the time of the operation. Dr. Strock said that having become infected in the latter manner, he applied for indemnity to the Preferred Insurance Company of New York, and was surprised when informed by that company that he was not entitled to any indemnity because the sepsis had not arisen as a result of his having wounded himself during an operation, but because the septic matter had entered through a previously unrecognized abrasion—the common method, by the way, by which a physician becomes infected.

Dr. WILLIAM J. CHANDLER of South Orange remarked that it was also the ruling of this company, that if the surgeon operates upon two cases the same day, and he cannot tell from which one he received the infection, they may decline to indemnify him.

Abuse of Medical Charities.—Dr. T. Y. SUTPHEN of Newark presented the report of this committee. He read a communication from the Cooper Hospital, Camden, stating that the managers of that hospital and of the Camden City Dispensary had been making an effort in the past few months to lessen the abuse of medical charity by making a personal investigation into the financial status of the applicants. It was found that many undeserving ones were deterred from applying, or from making more than one visit. A report from the Essex District Medical Society estimated that one in every five of those applying for medical charity were undeserving. Dr. Sutphen said that his committee still felt that legislation would afford the best and most speedy remedy, but in view of the radical differences of opinion on this subject existing among the members of the State society, his committee would not bring up any draft of a bill at this time.

Milk as a Food and a Means of Contagion.—Dr. R. C. NEWTON of Montclair presented the report of the committee having this subject under consideration. He said that while the weight of authority was against the declaration of Koch that there was no danger of infecting human beings with bovine tuberculosis, there was still a good deal of evidence on the other side. The report advised that the temperature of milk be taken when delivered to the creamery by the dairymen, when leaving the creamery for the cars, while on the cars, and when delivered to the consumer. If the temperature of the milk rose at any time above 55° F., or if the bacteria amounted to over one million per cubic centimeter, an inspection should be made to determine who was at fault. The committee recommended that the society issue circulars of information on the milk supply, and have them printed in the secular press, as the great point, after all, was to educate the public as to what was needed. Milk should not contain any preservatives or have an acidity over 2.1 per cent., and should not be over thirty-six hours old when it reaches the consumer.

President's Address.—The Nervous System in Its Relations to Medicolegal Medicine.—Dr. JOHN D. MCGILL of Jersey City delivered this address. He said the subject was conveniently divided for study into two great divisions, viz., (1) Physical and (2) psychical. The muscular reflexes constituted the most important class of symptoms by which to determine the character and localization of nervous diseases. However, reflexes might be inhibited as well, and hence this introduced a common and important source of error. Disease or injury to a particular nerve might be determined by the limitation to areas supplied by the nerve. Functional disease of the nervous system being founded on subjective symptoms was the cause of much trouble in medicolegal practice. There were many mental perversions which could not be classed under any of the usual forms of insanity. The definition of insanity generally accepted by medical scientists differed from that accepted by the law as competent and valid. A careful examination into the patient's physical and family history was essential. It was well, as a general rule, to determine the existence of any diathesis, and also to test the functions of the various organs, particularly those of the special senses, and this examination should include an exhaustive inquiry into the condition of the nerves and muscles. The presence of a delusion or a hallucination did not in itself prove the existence of insanity. In the insane the process of mental action was illogical, since it was founded on a false basis. An action for damages had been held to be valid if the evidence showed the existence of psychical shock as a result of the injury.

Progress in State Medicine and Hygiene.—Dr. EDWARD E. WORL of Newark presented this report. He said that the time was ripe for the establishment of a system of sanatoria for consumptives.

A New Treatment for Tuberculosis.—The Newark Board of Health was experimenting with a new method. It was known that a certain proportion of tuberculous persons die from the direct effect of the germs. Acute miliary tuberculosis was an example. In the new method of treatment toxins are taken from selected portions of tuberculous sputa, placed in an incubator for five days, and sterilized with 5 per cent. carbolic acid and filtered through porcelain. This preparation has feeble toxic power. Small doses are first injected into horses and the doses are gradually increased, and at the same time tuberculin is injected in increasing doses. After some weeks some of the blood is drawn and tested on guinea-pigs to prove that the preparation is harmless. Upward of sixty patients had been treated by this method during a period of six months, and all but three had shown physical improvement. Of course, this method of treatment was as yet in an experimental stage, and it was most important that the cases should be selected. The object of the treatment was to overcome at first the effects of the mixed toxins, and then to seek to immunize against tuberculous infection *per se*.

Smallpox.—The smallpox introduced into this country recently from Cuba had been of an unusually mild type, even among unvaccinated persons, and the black race had been favored by it. Since its introduction, however, the disease had become more severe. He had taken the histories of 200 cases and had carefully examined their vaccination marks. It was found that ninety-nine had not been vaccinated. Out of the 209 cases, thirty-six died. There were twenty-seven who had never been vaccinated; six had been vaccinated in childhood; twenty-six were white and ten were colored. It should be noted that smallpox does not always protect against itself. The fact that one was unable to be vaccinated even after several attempts did not necessarily mean that the person could not take smallpox, for the protection conferred by vaccination is in proportion to its efficiency. The time had certainly come when vaccination should be made compulsory The antivaccinationists should be placed in a colony by themselves that they might enjoy having smallpox without danger to others, and at the same time they should be allowed to pay their own expenses

Medical Inspection of Schools.—Out of 7,413 children excluded from the schools as a result of medical inspection it was found that 50 per cent. were excluded because of vermin, while only 2 per cent. were excluded because of having measles or scarlet fever. A study of the records showed that the results were certainly disappointing as regards the early detection of infectious diseases.

Progress in Diseases of the Nose and Throat.—Dr. B. A. Waddington of Salem read this report. He recommended the use of pure ichthyol as the best application in that most intractable disorder, atrophic rhinitis. The Roberts and Gleason operations seemed to give the best results in cases of deviated septum. The use of supports afterward was considered useless, and probably harmful. Where suprarenal extract or adrenalin was not at hand, epistaxis could often be promptly controlled by filling the nostril with vaselin.

Progress in Diseases of the Eye and Ear.—Dr. Talbor R. Chambers of Jersey City presented this report. He said that it had been recently claimed, as a result of experimental study, that the fluid in the anterior chamber of the eye comes from the anterior surface of the iris, and that the ciliary body is not a secreting organ. The value of removal of the superior cervical ganglion for glaucoma was receiving very serious consideration, and in the early part of the present year it had been reported that seventy-four cases had been so treated with only one death. It was not indicated in acute glaucoma except when iridectomy was refused or had been done on the other eye, and had not proved successful. A careful investigation as to the effect on surgical instruments of boiling them had demonstrated that there was little liability to rusting if the instruments were boiled in an alkaline solution, preferably one of carbonate of soda, and that the temper would not be injured if the instruments were not directly in contact with the bottom of the vessel. The dulling of knives by wiping them after boiling was greatly underestimated. With regard to the treatment of cataract it was asserted that the stimulation of the circulation by massage and electricity and heat were methods only possessing theoretical value. The importance of preventing mastoiditis was to be inferred from the fact that the four thousand deaths in this country annually from abscess of the brain were attributed to this cause, and that 50 per cent. of deaf mutes were so afflicted from the same cause, and that 20 per cent. of the pupils in our schools had defective hearing. Lumbar puncture had been recommended as a means of detecting the presence of a complicating meningitis. The presence of meningitis was indicated by the fluid being more or less cloudy.

Progress in Bacteriology.—Dr. Mazyck P. Ravenel of the University of Pennsylvania presented this paper. He said that a great deal of interesting work had been done recently on the differentiation of various kinds of blood by their agglutinating reactions. He believed it was already possible to differentiate between human blood and the blood of the lower animals, and also to distinguish between different kinds of meat. thus enabling one to detect substitution in the markets of one kind of meat for another. Certain bacilli had been isolated from cases of dysentery in widely separated parts of the world, and this had settled pretty clearly the cause of certain forms of dysentery. There could be no doubt that the mosquito was the true conveyor of yellow fever from the sick to the well, although the cause of this disease had not yet been discovered. The greatest honor and credit should be given to Dr. Walter Reed, U.S.N., and his co-workers in connection with this highly important and original work. With regard to rabies, the speaker said that the cause of rabies had not yet been discovered, but a positive diagnosis could be made in from twenty-four to thirty-six hours, and in urgent cases even in twelve hours. With regard to tuberculosis, Behring maintained that Koch was wrong in his statements of a year ago, and that bovine and human tuberculosis are intercommunicable, and at the live-stock laboratory in Pennsylvania they had obtained from two children, dying of intestinal tuberculosis, tubercle bacilli, which would kill grown cows in eighteen days. From the evidence that could be gleaned from the literature he was compelled to say that the local infection of bovine tuberculosis was far greater than that produced by human tuberculosis; hence, man certainly has something to fear from bovine tuberculosis, and this subject merited more attention than had ever been given to it before.

Some Diseases of the Fallopian Tubes.—Dr. Philander A. Harris of Paterson presented this report with lantern slides.

The Pathology of Appendicitis.—Dr. George E. McLaughlin of Jersey City had intended in this paper to give the results of a histological research in fifty cases, but, owing to the lateness of the hour, he contented himself with brief comments upon a series of lantern slides.

Second Day—Wednesday, June 25.

The Rural Surgeon; His Place, Privilege, and Duty.—Dr. A. W. Taylor of Beverly presented this essay. He declared that anæsthesia, antisepsis, and the trained nurse had revolutionized surgery. The general practitioner in the country should attend not only to his medical cases but to all ordinary minor surgery. The author described how easily even major surgery might be carried out by the rural surgeon. For the rural surgeon to send all of his surgical cases to the city surgeon or to a hospital was a shirking of duty and an imposition upon the charitable persons who support such institutions. and often in this way, moreover, the rural surgeon did not give that prompt and careful aid which his patient had a right to expect from him. A clear-headed and clean-handed woman could be found in almost every district, and would be found in an emergency an excellent substitute for the trained nurse, though the latter, when within reach, was an excellent aid. The country physician must consult his library by night and meditate by day. The author said that his faith in the country doctor was very great, and he was positive that too little was thought of the judgment, pluck and ingenuity of the country doctor. It was true that the country doctor would hear a little more of his failures than the city surgeon, but he would also hear a great deal of his successes, and the latter would aid him a great deal more in a financial way than the hard-fought battles with pneumonia and other diseases in the shade and obscurity of the sick room. The city surgeon comes, operates, and quickly departs with both the glory and the cash.

The Present Methods of Education from the Standpoint of the Physician.—Dr. Joseph Tomlinson of Bridgeton was the author of this essay. The observations of Dr. Robert W. Lovett of Boston on fatigue in school children were quoted. These show that school children very quickly exhibit mental fatigue, and that the mistakes occurring in dictation were 30 per cent. greater in the afternoon than in the early morning. The work of the school child, taking into consideration both school and home work, closely approximates the legal day's work of the laborer. The author pointed out that the limitations of sex were totally ignored in the present school system. A great defect in this system was the multiplicity of studies. The acquisition of facts rather than mental discipline was considered of chief importance. The baneful influence of examinations over school life was dwelt upon and strongly emphasized. The classification of pupils, he thought, should be made partly on a psychological basis. This would exclude certain pupils who really should be in institutions for the feeble-minded. The multiplicity of studies, the system of examinations, and the lack of classification of pupils were considered to be the three most important defects of our school system. The remedy was to be found in the private efforts of physicians and by appropriate legislation.

Dr. R. C. Newton of Montclair said that he had long felt that our entire educational system was defective in that there was too little individualization. Uniformity was the bane of the modern school teacher. But another very serious defect was the foolish desire to excel. A boy's development into manhood was slower than the development of the girl into womanhood, and hence the drain on his physical powers by our school system was not so great. The girl was not only naturally more feeble in her physical being, but her training, dress, and environment, all tended to aggravate this.

Dr. Dowling Benjamin of Camden said that he had noticed that chorea and other nervous disorders were particularly prevalent just after the promotions of the public schools. The great trouble with the schools was their faulty grading and the lack of uniformity in text books and methods of teaching in the different classes, thus throwing a great and unnecessary strain upon the pupils on passing from one class to another. The medical inspection of the schools at Camden was unsatisfactory because the matter of diagnosis was left to the teachers, and every physician knew that diagnosis was not the easiest part of his work.

Dr. E. J. Ill of Newark called attention to the foolish straining to raise the standard of our medical schools above a practical and reasonable level, and commented upon the fact that four students at a New York medical school had recently committed suicide.

The subject matter of this paper was referred to a special committee of five, with instructions to report at the next annual meeting

Valvotomy as a Surgical Measure for the Cure of Obstinate Constipation.—Dr. William M. Beach of Pittsburg presented this paper, and demonstrated the valves upon a patient. The author defined obstipation as "the inability to evacuate the bowels by reason of intrarectal obstruction due to valvular obstruction." The number of valves varied; he had observed six. The rectal valve, he maintained, was a definite anatomical structure, though Mathews and Bodenhamer denied that these valves possessed the essential structure of valves. The difficulty experienced in certain cases on attempting to inject a quantity of water into the rectum was due to an effort of these valves to prevent the entrance of the water. This could be demonstrated by inspection with the proctoscope. A dried specimen of these valves was exhibited. The physiological evidence of the rectal valve in man was the support of the fecal column with the person in the erect position. Rectal colitis, due to sigmoid procidentia, was, in his opinion, responsible for more reflex disorders than any other rectal trouble, and was especially difficult to treat. The systemic symptoms observed were usually dependent upon intestinal toxæmia. There was a general impression that simple divulsion of the sphincter ani would cure obstipation, but a simple trial would convince any one of its inefficiency. On the other hand, valvotomy would prove effective. The technique of this operation was simple, but like other operations a certain amount of experience was necessary to insure complete success. The patient is placed in the knee-chest position, and a four-inch proctoscope having a caliber of 1⅛ inches is inserted. The valve is brought into view and is sprayed with a 1-per-cent. solution of eucain, and then with a 1-per-cent. solution of suprarenal capsule. By means of a test hook the depth of the valve is determined. Two incisions are made in each valve, and one suture is used on each side to unite the broad wound and prevent a large granular surface and possible peritonitis. The dangers are hemorrhage and peritonitis. The tissues are very vascular, but the free use of suprarenal solution followed by tamponade will usually suffice. Considerable judgment was required in determining the requisite depth for the incision. After the operation the patient should receive a daily enema and a saline for a short time. He had met with a number of cases of amenorrhea and dysmenorrhea in which relief had been afforded by valvotomy, a fact which, so far as he knew, had not been noted heretofore.

Further Report on the Use of Ethyl Bromide as a Primary Anæsthetic.—Dr. Emery Marvel of Atlantic City read this paper. The method employed by him consists in pouring a fluid drachm of ethyl bromide on a piece of gauze in the palm of the hand, and holding this over the patient's face. Unconsciousness is soon produced, and after that either ether or chloroform is substituted. The advantages claimed were: a shorter time to secure anæsthesia, less discomfort to the patient, a smaller amount of ether used, a more rapid return to consciousness, and a decreased tendency to vomiting after etherization. He had employed this method in thirty-three operations, thirty of which were laparotomies. The ages of the patients ranged from five to thirty-seven years. Women were much more easily affected by ethyl bromide than were men, but the same seemed to be true of ether and chloroform. The average quantity of ethyl bromide required was two drachms, and the average time to secure unconsciousness was twenty-five seconds. One person proved not to be susceptible to the influence of ethyl bromide, but subsequent inquiry showed that the ethyl bromide had been exposed and was probably not in proper condition Only occasionally were dyspnœa and cyanosis produced, and in only one instance was cough excited.

The Cause of Sore Arms During the Recent Vaccinations.—Dr. Alexander McAllister of Camden presented this report. He said that a period of twenty years or more of growing indifference to vaccination had suddenly terminated by an urgent demand for vaccination, and never before in the history of the world had so many been vaccinated in a like period of time. The remarkable proportion of "takes" and the mildness of the sore arms, which the literature led us to expect, were not realized in these recent vaccinations. In every recent instance in which tetanus complicated vaccination it was shown that secondary infection had taken place. The most common cause of excessively sore arms was skin cocci, which may be present in the vaccine virus, or might be introduced at the time of vaccination. It could not be guaranteed that glycerinized virus would be free from these cocci. The most carefully-shielded arms were usually the sorest. Antiseptic precautions usually ended with the insertion of the virus, even when shields were used. In view of these facts, it seemed to the author little short of miraculous that so few vaccinations do not heal kindly.

Dr. A. K. **Rogers** of Paterson thought if very little blood was drawn and the scarification was small there would seldom be a very sore arm.

Dr. A. I. **Hunt** of Hamilton Square said that when he had used glycerinated virus in tubes there had been no sore arms, but there had been more occasion to revaccinate.

Dr. **Cornelius Shepherd** of Trenton said that during the greater part of his forty years' experience he had made use of human virus, and although he had attended almost one hundred cases of smallpox this mode of vaccination had effectually protected him against the disease. With the use of human virus he had almost never seen unnecessarily sore arms, or other complications, but his experience in recent years with bovine virus had not been quite so favorable, and he was inclined to think that the continued use of bovine virus might ultimately lead to great opposition to vaccination. He had not used shields, or resorted to antiseptic or aseptic treatment.

The Cure of Cancer by the X-Ray.—Dr. **Dowling Benjamin** of Camden read this paper. He said that, so far as could be ascertained from published cases, about twenty undoubted cases had been cured, and four others had remained over two years without relapse. Since the *x*-ray could pass through six inches of wood and burn the human body without burning the wood, this powerful agent must necessarily influence cancer, even if deeply situated.

Dr. **Talbot R. Chambers** of Jersey City said that while his personal experience with this new method had been limited and not favorable, he had recently been informed by Dr. J. E. Stubbert that it was possible to pass the *x*-ray through a speculum and then bend the ray to focus it on a particular part. This should prove a valuable addition to the technique.

Radical Operation for the Relief of Chronic Purulent Disease of the Middle Ear.—Dr. F. C. **Ard** of Plainfield was the author of this paper. Four illustrative cases were reported, and the point insisted upon that there was practical uniformity of opinion among the best authorities regarding the seriousness of a chronic purulent otorrhœa and the necessity for prompt operation. Such a discharge might be odorless and still be highly infectious. Preventive treatment was, of course, the best of all, and this involved the proper treatment of otitis media.

The Cause and Treatment of Sterility in Women.—Dr. **Edward** J. **Ill** of Newark presented this paper. He said that about 12 per cent. of his own patients were sterile after two years of married life, and that about one-sixth of all the cases presenting themselves were absolutely or partially sterile. The woman should not be pronounced sterile until assured of the normal functional condition of the husband. Having excluded the husband as the source of the sterility the physician should inquire into the sexual relations of the husband and wife. It was frequently stated that an acid secretion of the vaginal secretions would result in the death of the spermatozoa, but he had been unable to verify this statement. Nor had he been able to substantiate the assertion that the discharge of semen from the vagina was any greater in sterile than in fertile women, and he would not lay any stress upon this. Of all sterile women, 18.3 pêr cent. had myomata. The subserous variety of fibromata was associated with the largest percentage of sterility, and the interstitial form with the lowest percentage. The author was not partial to myomectomy done through the vagina, the scar being decidedly objectionable, as well as the fact that the uterus was often drawn from its position. There would be less wounding of the pelvic cellular tissue when operating through the abdomen. Tumors near the horns of the uterus and such as produce extreme displacements promise well for the cure of sterility by the removal. The operation was not advised for the cure of sterility when there were many nodules. In his own experience 17 per cent. of the cases of sterility were due to inflammatory disease of the tubes and ovaries, most frequently of gonorrhœal origin. Gonorrhœa, and more rarely septic infections, were the chief causes. Thickening of the tunica albuginea and hypertrophy of the cellular tissue of the ovary were apparently the chief pathological conditions in the ovary connected with sterility. Dr. William M. Polk had deliberately recommended laparotomy for the sole purpose of relieving sterility, and while such a procedure might be proper in the hands of Dr. Polk, one should be careful about recommending indiscrimately such radical surgery. So far as he could learn the cases in which other surgeons had, for the most part, practised conservative surgery on the tubes and ovaries he had been accustomed to refrain altogether from operating.

Dr. **George** H. **Balleray** of Paterson directed attention to what he called "relative sterility," *i. e.* the condition in which a woman is sterile while married to one man, and afterward becomes pregnant with a second husband. Of all the varieties of displacement causing sterility, congenital anteflexion had proved the most rebellious in his hands. Cases of posterior displacement could be successfully treated by the proper application of a pessary. Infantile uterus as a cause of sterility was far from uncommon. Many of these women present a healthy appearance, and good development of the breasts, and in most instances menstruation is regular, though scanty.

Report to the State Society of the Cases of Tetanus Following Vaccination in Camden.—Dr. A. E. **McAllister** of Camden presented this report. There were ten cases of tetanus in persons recently vaccinated. Eight cases ran a short course and terminated fatally; the other two ran a more protracted course. The cases all appeared in the limits of Camden during the month of November, 1901. The ages ranged from five to sixteen years, and all were white with one exception. In at least seven cases glycerinated virus from tubes had been employed, and in all antiseptic precautions had been taken. In one case tetanus complicated a gunshot wound of the foot. In several instances portions of the packages of virus from which the vaccinations had been made were secured, and they were submitted to the bacteriologist of the State Board of Health. In cases Nos. 1, 4, and 9 another member of the family was vaccinated at the same time with the same virus and in the same manner, and only a typical vaccination sore was the result. In one instance the second vaccination was made from the same tube, yet no tetanus developed in this second party. In every instance in which tetanus occurred, the vesicle had been broken. The tetanus invariably broke out in from two to three weeks after the vaccination, while the period of incubation of tetanus is from two or three days up to, but not exceeding, ten days. The bacteriological examination showed the virus used to be free from tetanus or other pathogenic germs. The committee on investigation was of the opinion that the shifting winds and dry weather, prevalent at the time of the outbreak of tetanus, favored the dissemination of the tetanus germs over the city of Camden.

A Plea for the Early Diagnosis and Treatment of Cancer of the Uterus.—Dr. **George** H. **Balleray** of Paterson read this paper. He said that nine-tenths of the cases of cancer of the uterus begin as cancer of the cervix, the result of traumatism. He did not believe that there was an authentic case on record in which carcinoma of the cervix had developed in a virgin cervix; the cases reported as such had probably occurred in women who had concealed the truth. The preventive treatment of cancer of the cervix should begin in the lying-in room. The os should be allowed to dilate normally, and when dilatation was slow and difficult, hot vaginal douches should be used, or morphine administered. If, in spite of care and skill, laceration of the cervix should occur, the patient should be kept in bed for four weeks, using large, hot vaginal douches, three times a day. Ninety per cent. of cases of recent laceration of the cervix would heal under this treatment. Rest alone was not sufficient because the lacerated surface would not properly heal if constantly steeped in the lochia. He had no confidence in the immediate operation for repair of the cervix, believing it to be impossible to properly coaptate the parts by suture. Next in importance to the preventive treatment of cancer of the cervix came that of early diagnosis. When cancer of the cervix was limited to the portio vaginalis amputation of the cervix gave good results. When the disease involved the vaginal walls no operation was of value. In cancer of the body of the uterus, hysterectomy, if early performed, was of great value.

Brain Abscess of Otitic Origin.—Dr. Wells P. Eagleton of Newark read this paper, reporting two cases. He said that a search through the literature showed that chronic suppuration of the ear was responsible for 84 per cent., and acute suppuration for the remaining 16 per cent. of the cases. Cerebellar abscess, for some reason, was apt to be multiple, and this fact explained many failures of operation. A large proportion of the cases were chronic, often remaining quiescent for months or years, and giving rise to few, if any, symptoms. In one case the only symptom was pain in the head over what proved to be the seat of the abscess. In another case, severe neuralgia of a molar tooth was the only symptom for a long time, and subsequently each dressing produced this same pain in the tooth. The brain tissue surrounding the abscess was sometimes the seat of multiple hemorrhages. Among infants, slight fever and gradual loss of flesh were often the only symptoms. The so-called localizing symptoms were unreliable. Outside of aphasia, which was present in 30 per cent. of the cases of tempero-sphenoidal abscess, these symptoms should not be relied upon. Operation should be done just as soon as the diagnosis has been made. The urgency of such cases was well illustrated by one of the cases reported, and by the fact that, in a number of other cases, the patients were already in the hospital, and the operation was fixed for the following day. In operating, the fact that, in the majority of cases, it is exploratory should be kept constantly in mind. Thus, in about 10 per cent. of the cases operated upon, the symptoms caused the surgeon to suspect the abscess to be localized in one fossa, when, as a matter of fact, it was in the other fossa. Of the cerebellar abscesses, 32 per cent. gave symptoms, such as paralysis of the arm, eye, hand, or leg. Out of the one hundred and one operative cases, failure to locate the pus on exploratory operation occurred in 21 per cent. This was owing to the fact that the pus was so thick that it would not pass through the aspirating needle, or to the fact that the capsule of the abscess was unusually thick and resistant. In some instances, even a director had passed through an abscess cavity without pus being detected. The surgeon was, therefore, justified in passing his finger into the brain substance when the abscess could not be detected by other means. It was important in operating to make a sufficiently large opening to secure perfectly free drainage. The opening in the brain should always be large enough to admit the finger of the operator for the purposes of exploration, and this having been done, it should be further enlarged in whatever direction would secure the best drainage.

Further Notes on the Hot-Water Douche for Aborting Mastoiditis.—Dr. Talbot R. Chambers of Jersey City presented this paper. He said that if the douche were used for twenty minutes at each seance, the water being at 120° F., it would very often abort purulent otitis media and acute mastoiditis, or exacerbations of chronic mastoiditis. It was necessary to use a bath thermometer to gauge the temperature, and the use of the return current ear douche was absolutely necessary to avoid blistering from the very hot water. Cases were reported showing the good effect of this treatment.

Dr. Walter B. Johnson of Paterson said that he questioned very much whether mastoid disease, once started, could be cured by any treatment which came no nearer to it than the drum membrane. It did not follow that a given case was one of true mastoid disease simply because pain and tenderness were present in the mastoid region, with inflammation of the ear and a certain amount of fever. The treatment advocated was, however, very useful in acute otitis.

Dr. N. L. Wilson of Elizabeth said that when there was acute congestion in the antrum, or perhaps in some of the mastoid cells, the condition might sometimes be aborted, but he had never known this favorable result to occur when pus was actually present in the mastoid cells. He often found it difficult to persuade his patients to submit to the use of the hot water ear douche when the water had a temperature of only 115° or 110° F.

Dr. Cornelius Shepherd of Trenton said that the hot ear douche was only intended to be used before abscess formation, and the condition for which it was used was comparable to tonsillitis where even a very severe attack may subside without suppuration.

The Surgical Treatment of Gastroptosis.—Dr. H. D. Beyea of Philadelphia was the author of this paper. He said that, according to our present knowledge, gastroptosis might be said to be a common cause of chronic invalidism. The causes were said to be tight lacing, changes in the intraabdominal pressure and relaxation of the recti muscles, and it was also thought to be sometimes a congenital condition. The patient was usually profoundly neurasthenic and suffered from severe atonic dyspepsia. Cold and hot intra-gastric douches were of some benefit. Both medical and mechanical treatment gave relief, but they were not curative, and hence he suggested a surgical treatment. At the suggestion of Dr. William Pepper, he had devised and practised in 1898 for the first time the operation described in this paper. Three rows of silk sutures are placed up and down and from side to side in the gastrophrenic omentum. Three cases had been operated upon by this method by him, and four had been operated upon in Germany by a similar method. In every instance the form of gastroptosis was the subvertical, and was pronounced, without relaxation of the abdominal wall or diastasis of the recti muscles. In every instance convalescence had been normal. The patients were kept in bed for from four to six months after the operation, and kept on a special diet. The improvement in health had been most remarkable, and the relief of symptoms complete. The danger of the operation was little more than that of an exploratory laparotomy, and was estimated to be about one-fourth of one per cent.

Dr. Emery Marvel of Atlantic City said that as gastroptosis was associated with dilatation of the stomach and atony of its walls there was a predisposition to gravitation and consequent stretching of the contracted ligament; hence, he thought, there might possibly be a secondary elongation of the shortened ligaments.

Dr. M. Lampson of Jersey City said that as six out of the seven patients were females the condition of gastroptosis was fairly comparable to that of prolapse of the kidney, a condition which had not yielded very satisfactory results from operation. Like all other efforts to correct a relaxed condition, often dependent upon faulty dress and general habits of life, the results of this operation must be uncertain.

Dr. Philip Marvel of Atlantic City suggested that some of the good result noted might be due to prolonged rest in bed and a special diet. It was for the surgeon to formulate the degree of gastroptosis and gastric dilatation which should be looked upon as an indication for this operation. In some severe cases of gastroptosis that had not been subjected to operation, great benefit had been known to follow the long-continued use of the lavage tube, at night especially. One of his patients had been subjected to the operation of suspension of the stomach, and since the operation, though possibly not as a result of it, there had been prolonged and uncontrollable vomiting.

Dr. R. C. Newton of Montclair called attention to the fact that, in health, the size, shape and position of the stomach were subject to considerable variation.

Dr. Beyea replied that his first patient had been treated by all the recognized methods for a long time before the operation, and that the improvement in her condition since that time had been remarkable and permanent. An examination made one year after the operation showed that the stomach had not descended one inch. Operations for floating kidney had been unsatisfactory largely because of a faulty technique in the past, though, he thought, this had now been remedied. Again, gastroptosis and prolapse of the kidney were often associated, and the anchorage of the kidney without correction of the gastroptosis, had led to disappointment. When the stomach was restored to its natural position by operation the normal tonicity of its walls returned. At the present time he only recommended his operation in cases characterized by severe symptoms, which are not relieved by a sufficiently long trial of medical and mechanical treatment. He thought most physicians would admit that, in most cases of gastroptosis, such treatment must be kept up indefinitely. No evil results had followed his operation, though they had been known to occur in connection with other operative methods which restrict the mobility of the stomach. Elevation of the stomach by shortening its natural ligaments was very different from fastening this organ to the abdominal wall.

Officers and Place of Meeting.—*President*, Dr. E. L. B. Godfrey, Camden; *First Vice-President*, Dr. Henry Mitchell, Asbury Park; *Second Vice-President*, Dr. A. W. Taylor, Beverly; *Third Vice-President*, Dr. W. B. Johnson, Paterson; *Corresponding Secretary*, Dr. E. W. Hedges, Plainfield; *Recording Secretary*, Dr. William J. Chandler, South Orange; *Treasurer*, Dr. Archibald Mercer, Newark. The next annual meeting is to be held at Asbury Park, on June 23, 24 and 25, 1903.

THE ASSOCIATION OF MILITARY SURGEONS OF THE UNITED STATES.

Eleventh Annual Meeting, Held in Washington, D. C.
June 5, 6, *and* 7, 1902.

Remarks by the President of the United States.—In opening the meeting President Roosevelt remarked upon the dual relations of the military surgeon as a soldier and physician. He referred to his personal observation of the high character of the surgeon's work in war, and especially commended the organization of an association with purposes such as this, remarking that "without this work of the Association you cannot give the highest expression to individual endeavor; and it would be a great misfortune if the military members of the surgical and medical professions did not take every advantage of their opportunities," and closed by commenting upon the necessity of cultivating the administrative side of the military surgeon's character.

Addresses of Welcome were made by Hon. H. B. F. MacFarland, President of the Board of Commissioners of the District of Columbia, and Dr. Samuel S. Adams, President of the District of Columbia Medical Society.

The President's Annual Address.—Under the caption of "The Broader Mission of Our Association," the President, Lieutenant Colonel John Van Rensselaer Hoff, U. S. A., discussed the recent unusual growth of the organization, and pointed out other lines along which its efforts should be extended. The need of continued improvement in the state forces, which should render the medical departments of all a uniform and progressive body, was emphasized. For the regular establishments, improvement also should be inspired, demanding of their personnel, commissioned and enlisted, the highest degree of efficiency; the Association must see that their organization and equipment must be even more perfect than those of any other nation; it must provide a means, through our medical schools, for the dissemination of a knowledge of military sanitation in the profession at large, so that every physician will know something of the work of the medical officer. Referring to the need for military medical schools on the lines of West Point and Annapolis, he remarked upon the necessity for the formulation of plans by which private aid may be made to supplement, not supersede, the public services in time of war or other stress, and closed with a reference to this function of the Association in affording common ground upon which the military humanitarians of the world might cooperate in mitigating "the horrors of war"—touching, by the way, upon the newly-adopted international feature in its membership.

The Most Practicable Organization for the Medical Department of the United States Army in Active Service.—This was the subject for the Enno Sander prize essays, and the gold medal was awarded to Lieut.-Col. Valery Havard, U. S. A., and honorable mention with a life membership in the Association was awarded to Captain Frederick P. Reynolds, U. S. A. Col. Havard's essay was a comprehensive treatise upon the subject in all its aspects, beginning with a general survey of the lines of surgical assistance on or near the battle-field, and discussing the casualties of battle and the transporation and the hospital accommodations required. He then took up the personnel, insisting that the sanitary personnel should number at least 4 per cent. of the strength of the command engaged. The material, including ambulances, litters, and other means of transportation, and the conduct of the medical department on the march and in camp were then taken up. After a full consideration of the principals of the first aid on the battle-field, he took under consideration the lines of surgical assistance in operation and the service of the rear, concluding with some remarks on foreign service.

Captain Reynolds began with a consideration of the field personnel of the medical department as a whole, including medical officers, contract dental surgeons, the hospital corps, companies of instruction, for which he laid down a comprehensive system of organization and training, female nurses, civilian employees, and ambulance companies. He then took up the field hospital and pointed out the best organization for the medical department on the lines of communication and at the base, including hospitals, transports, supply depots, and reserve personnel. Based upon the conclusions thus deduced, he presented a detailed outline scheme for the medical department in active service, in camp, on the march, and in action. The paper was particularly remarkable for its grasp of the vast detailed work of the military medical officer, details little understood by the civilian, but essential to the success of the work of the military surgeon.

Education of Medical Officers for the Public Services.—Medical Director John C. Wise, U. S. N., gave a full decription of the military medical schools of France at Rochefort and later at Toulon and Brest; the English schools at Netley and Hasler for army and naval medical officers respectively; and the Friedrich Wilhelms Institute for German medical officers. From the history and character of these institutions, he concluded that modern circumstances demanded a high degree of special knowledge upon the part of the military officer, requiring the facilities already offered by the post-graduate medical schools of the army and navy to be greatly expanded, and opened to surgeons of the national guard and naval reserve, as well as to the officers of the regular establishment.

The Executive Element in the Training and Skill of a Military Surgeon.—Dr. John N. Goltra, U. S. A., held that: (1) The duties of an army surgeon are largely administrative; (2) The duties and requirements of the army surgeon demand and justify the widest practical authority it is possible to give him; (3) To the greater degree of authority should be added a better executive training.

In discussion, Colonel Havard, U. S. A., commented upon his experience while Chief Surgeon of Cuba, where but three or four out of twenty-five hospitals were under the command of trained medical officers, and remarked upon the great improvement that would have attended the sanitation of the forces had the remaining medical officers possessed the requisite executive training.

Major Appel, U. S. A., described the discipline of the army sanatorium for tuberculosis organized by him at Fort Bayard, N. M., and dwelt upon the great importance of a strong administration in the treatment of such cases.

Colonel Nielson, Surgeon General of Canada, spoke of the difference between the conditions existing in the regular forces of the United States, and those prevailing in militia of Canada. Newly-appointed militia surgeons are required to take a course of special instruction of ten hours a day for seven days. These courses are repeated every year, and ultimately result in a very considerable degree of efficiency.

Captain Munson, U. S. A., referred to and emphasized the remarks of President Roosevelt along this line in his opening address.

Lieutenant-Colonel Jarvis, N. Y., remarked upon the recognition of the necessity for administrative training in the newly-commissioned medical officers in the New York City brigade of the national guard, in the examination of whom military hygiene plays a very prominent part.

Captain Jarrett, N. Y., commented upon the danger, in military service, of losing sight of the professional side in over-consideration of the executive side of the work of the medical officer.

Major Ames, U. S. V., emphasized the equal need for professional and executive qualifications, and warmly endorsed the views of Dr. Goltra, deprecating a tendency in some quarters to undervalue them.

The Ideal Relation for the Medical Department of an Army.—Major William O. Owen, U. S. A., observing that the greatest loss of life in military operations was due to the neglect of line officers in command to carry out the sanitary recommendations of medical officers, proposed the enactment of a law that will enforce upon the commander a direct legal personal responsibility for his refusal to allow proper sanitary precautions to be taken, leaving him always the absolute right to refuse all sanitary suggestion whenever there is, in his judgment, a military necessity requiring it; allowing him to be the sole judge of when and under what conditions it should be done; holding him to a legal responsibility that his results are good ones; but not leaving him such a latitude as will allow him to go unpunished when he deliberately set at defiance all the rules recognized by sanitarians the world over, or when, by his deliberate personal example, he encouraged his men to violate them.

Character Study in the Examination of Persons for Military Service.—Medical Inspector F. B. Stephenson, U. S. N., advocated the inclusion of the indications of character in the examination of recruits. The experienced eye detected in the physique of a man and his manner of using the various parts of his body indications of his mentality, and of his moral and intellectual qualities. The form of various portions of the body indicated the innate trend of the person—mental and moral. The effects of environment might be seen in the expression, not only of the face, but of all other parts of the organism—the head, hands, feet, various postures of the body, the gait, gestures, and the like. The value of adding a consideration of these points to the physical examination of recruits as now conducted, the author believed to be very great.

The Recruit.—Lieutenant S. C. Stanton of Chicago particularly emphasized the danger of youth, especially in commands destined for tropical service. He believed, moreover, that the experience of medical officers of all countries and in all climates had shown that soldiers of mature age are much less susceptible to disease and possessed of greater resistance to the hardships of field service than less-developed individuals. Lieut. Stanton was examiner of recruits for the army at Chicago, and a proposed blank for the physical examination of recruits for the National Guard, which he submitted, carried the weight of large experience with it.

Colonel Exham referred to the importance of defects unimportant in civil life, but the source of much military disability; in South Africa such defects caused no less than 30 per cent. of some organizations to be sent home. The extent of disability from defective teeth was something enormous.

Medical Inspector Dickson especially endorsed the point taken concerning defective teeth, a defect which is particularly embarrassing in the naval service, and to which more attention should be paid by examining surgeons.

Colonel Almy thoroughly endorsed what had been said concerning the teeth, and referred also to the importance of defects of the feet.

Medical Director Wise emphasized the disadvantage of varicocele in the recruit.

Major Borden believed that any person having a predisposition toward disability should be rejected by an examiner of recruits. He pointed out the injustice to the government of accepting men with slight disqualifications who might afterward become candidates for pensions and a burden upon the nation; in case of discharge for disability, the man should be given the benefit of any doubt that may arise, but in the case of enlistment the government should be given the benefit of the doubt.

The Nurse Corps of the Army.—Dr. Anita Newcomb McGee, who organized the body of female nurses during the Spanish War, gave a brief account of the development of the army Nurse Corps, consequent upon that work. She recommended the utilization of the woman nurse as an instructor of hospital corps men in that branch of their duty, advised post-graduate work in a military hospital for regular graduate nurses, and urged the employment of a permanent teaching force, including perhaps 100 nurses, appointed for life and stationed for service at certain large hospitals, where they may also be available for detached service if needed. In addition to this, provision should be made for a war reserve, to be gradually created by admitting trained women nurses to army hospitals in a constant succession of squads, of such size as might be desired, for a military post-graduate course, each nurse upon finishing the course to become a permanent member of the reserve, until the suggested number of two thousand was reached.

Colonel Exham spoke of the increased demand for women nurses in the British Army, and referred warmly to the value of their services.

Captain Standish commented upon the advisability of utilizing trained women nurses as teachers of nursing, and expressed himself in favor of specialization in instructing the enlisted hospital men, training some as cooks, others as nurses, etc.

Colonel Havard commented upon the work of the woman nurse in Cuba and advocated their employment in large hospitals, but considered their presence inadvisable at post hospitals and impossible at ambulance stations and on the firing line.

Colonel **Weaver** referred to his experience with women nurses at Camp Meade and took a position strongly in favor of them.

Colonel **Hoff** considered the woman nurse as an indispensable feature of military hospital work in war, and believed that during peace women nurses should be kept in constant training to serve as a nucleus of instruction and direction for the greatly-expanded corps that will be required upon the declaration of war

Organization and Conduct of a Medical-Supply Depot.—Colonel J. Morris Brown, U.S.A., the chief medical supply officer of the army discussed the subject of army medical supplies under the heads of organization, purchases, storage and issues, and closed with a brief account of his own experiences, during, and since the Spanish war. The absorbing character of the work was shown by the execution of an order to ship at once to Montauk Point four division hospitals complete with a large amount of additional articles. Work was begun on the order at noon, and at six o'clock the next evening 309 packages were shipped, many of them of large size and containing thousands of articles. An interesting list of articles supplied during the war was given, including twenty-five million quinine tablets, nearly two million compound cathartic pills, and other articles in similar amount.

The Army General Hospital and Sanatorium for the Treatment of Pulmonary Tuberculosis at Fort Bayard, N. M.—Major Daniel M. Appel, U.S.A., described in detail the Fort Bayard Sanatorium, organized and equipped by him under the direction of the Surgeon-General of the Army. The climate of Fort Bayard permits of comfortable out-door life during the entire year, with the exception of a short period of high winds during the spring. The patients are divided into three classes: (1) A febrile without tubercle bacilli in the sputum; (2) A febrile with tubercle bacilli in the sputum, and (3) Permanently febrile with tubercle bacilli in the sputum; the first class have separate dormitories and the third class are confined to the infirmary. It was designed to admit to the sanatorium all cases from other army hospitals, regardless of the stage of the disease or their desire to come. The results of treatment were largely modified by the difficulty of retaining patients after discharge from military service and by the excessive use of alcohol. Abundant nutritious food and entire rest were inculcated, and a uniform course of breathing exercises was required. Pocket paper spit-cups and frequent cuspidors were abundantly supplied and frequently cremated. Life in the open air was the keynote of the treatment. Hæmoptysis was rare as compared with lower altitudes, and night sweats were unusual and readily amenable to treatment. Continued observation encouraged the conviction of the increasing number of cases amenable to treatment in a high, dry climate.

Military Medical Conditions in the South-African War.—Colonel Richard Exham, C.M.G., the delegate from the British Army, referred to the effect of the use of long-range heavy guns throwing large shells, upon medical field arrangements, in increasing the distance of the field hospitals from the front, and in extending the field from which the wounded have to be collected. The latter condition was also contributed to by the fact of the majority of the Boer forces being mounted, all of which demanded a relative increase of the bearer companies; the increase need not necessarily be in specially trained medical corps men, but might consist of specially enlisted bearers or, preferably, men of militia or volunteer staff corps. He thought that in future the bearer company and the field hospital would be consolidated into a single unit, divisible into two or four complete sections in case of necessity, whose duties would consist of the care of the wounded only until a permanent field hospital capable of accommodating 200 beds should arrive. These should, in turn, evacuate into general hospitals rapidly established along the lines of communication as the army advances. In South Africa great inconvenience was endured on account of insufficient service of this kind. He dwelt upon the importance of having suitably-fitted hospital railway trains and ambulance ships available for use. Convalescent camps along the lines of communication were of the greatest assistance in South Africa. He referred to the need of an ambulance adapted to roadless country, and stated that prizes were offered by the British government for the best vehicles for this purpose. The difficulty of obtaining suitable drinking water was shown by the fact that it was necessary to clean the water by filtration through ordinary sheets, but its sterilization could not be satisfactorily effected either by filtration or by boiling. He concluded by briefly alluding to the questions of (1) the rules governing the retention of captured field hospital, and (2) the carriage of the arms of the wounded in ambulances, which were to be brought before the next meeting of the Geneva Convention.

A Canadian Transport and Ambulance Wagon.—Colonel J. H. L. Nielson, Surgeon-General of Canada, described a combined transport and ambulance wagon devised by him for the tenth field hospital of the Canadian Military Medical Corps. The wagons were very light, readily taken apart and packed for transportation, and carried four recumbent patients and a considerable number of important accessories. These wagons were tested in the South-African operations and met the test excellently. The author also briefly described the water cart and a forage cart used under his directions.

The Army Cartridge Belt.—Major Louis L. Seaman, U. S. V. E., objected to the wearing of a belt full of cartridges about the abdomen without other support than that afforded by contact with the abdominal walls, contending that the present practice was a prolific source of intestinal catarrh and diarrhœa. He recommended the attachment of some form of suspension from the shoulder.

A New First-Aid Packet.—Assistant Surgeon J. C. Thompson, U. S. N., who was on duty with the United States forces during the China relief expedition, found the first-aid packets furnished the troops to be unsatisfactory, and proposed as a substitute a stout muslin bandage four yards long and two and one-half inches wide. At a distance of eight inches from the end was incorporated a pad four and a half by seven inches, and just beyond this pad was another not fastened but run on a slide, which allowed it to be moved along the bandage, so that its application to a wound of exit at any distance could be made with the utmost rapidity, or, should there be only a single lesion, it might be applied overlapping the permanent pad, thus giving a dressing of considerable stability. The compresses had a backing of stout waterproof material and were lined with several layers of sublimated gauze, which was folded upon itself many times over its middle third, so as to form an extra padding of absorbent material. The outer third of each compress formed two flaps, which were folded around, one over the other, thus protecting until the last moment the surface intended for application to the wound.

A New Field and Navy Litter.—Passed Assistant Surgeon C. Alexander Crawford, U. S. N., demonstrated a new litter of his invention, with a frame work of steel tubing, which was complete in itself, all its parts firmly united and ready for instant use, and yet of a suitable shape and of a sufficient lightness to be carried for hours, like a knapsack, upon the shoulders of one man; in addition it could be raised and lowered through any hatch, slid along deck, or employed singly or in tiers, as a swinging-cot in the sick-bay with perfect safety to the wounded. The litter, folded in the middle, had straps for retaining the patient in place and attachment for lowering and raising through hatches, and was equally well adapted to be carried by two, four, or six bearers.

The Management of Smallpox.—Passed Assistant Surgeon C. P. Wertenbaker of the Marine Hospital Service presented a sharply-drawn picture of smallpox as usually found, with directions for its care, in such shape that they could be easily remembered and utilized in time of need. He had no set method of treatment to propose, preferring to meet the symptoms as they might arise. He dwelt upon the value of orange juice as a diet, remarking that he had kept a patient in excellent condition for thirty days on this diet. The management of smallpox in detail and at large was carefully considered, the entire subject being compressed in conclusion into the three words, "isolate, vaccinate, disinfect."

The Vaccination of Porto Rico—Lesson to the World.—Major Azel Ames, U. S. V., gave a vivid account of the extirpation of smallpox in Porto Rico, under the direction of Colonel Hoff, and by means of lymph produced under the direct supervision of the author. He summarized the work by stating that in October, 1898, smallpox was endemic in Porto Rico; in December it was epidemic; in January, 1899, it had honeycombed the island; by February there were over 3,000 recent cases, and the disease was spreading at a gallop. In February systematic compulsory vaccination, carefully and scientifically conducted and recorded, was begun simultaneously and with pretty equal efficiency in all parts of the island. It was vigorously prosecuted for four months only, till July 1, when 860,000 vaccinations had been made in a population of about 960,000. Of these $87\frac{1}{2}$ per cent. were successful. The work then ceased—because completed; the disease had practically disappeared; the fuel for it to feed upon had been consumed by the "head fire" of vaccination In the two and a half years that have since passed, instead of the former annual death rate of 621 the mortality from smallpox has been but two per annum in a population of nearly a million. Vaccination, in four short months, drove smallpox from its wide and long-time reign in Porto Rico, and has since kept it out—a brilliant illustration of the adequacy and efficiency of the general compulsory application of such treatment.

Yellow Fever.—Dr. James Carroll, U. S. A., who was not only a member of the Army Yellow Fever Commission which brought the mosquito theory of transmission before the public, but offered in himself the first case of experimental yellow fever produced by the sting of the Stegomyia fasciata, read a scholarly paper upon that subject. He reviewed the history of epidemics of the disease from the middle of the seventeenth century to the present time, discussing the work and results of Freire, Sanarelli, Sternberg, Finlay, Reed, Agramonte, and himself and its progress to the present assured etiological situation, and concluded that yellow fever was contracted only through the bite of an infected mosquito twelve days or more after feeding upon a patient in the early stage of the disease. Fortunately, many of the mosquitos of the genus Stegomyia did not appear to live long enough after biting the patient to be capable of communicating the disease to other individuals. After feeding upon blood they soon proceeded to deposit their eggs and, in performing this function or soon afterward, a large proportion of them died. The duration of life of the insect, exclusive of hibernation, was probably not more than seventy-five days under the most favorable conditions. It might be capable of infecting as early as twelve or fourteen days after biting, and might retain its power to communicate the disease until the fifty-seventh day after the first feeding upon a yellow-fever patient.

Some of the Experiences of the Navy with Yellow Fever Aboard Ships.—Surgeon F. W. F. Wieber, U. S. N., after a careful search of the reports of the medical officers of the navy upon the cases of yellow fever observed on shipboard, arrived at the following conclusions: (1) Persons on board of a ship anchored some distance from shore in a yellow-fever port may become primarily infected with yellow fever without having set foot on shore; (2) The infection thus caused can be traced directly or indirectly to the taking in of stores and provisions; (3) Secondary cases have frequently happened on board ships anchored at a considerable distance from shore; (4) Epidemics on board men-of-war have been prevented by the timely isolation—sending on shore—of early cases; (5) In some cases an epidemic has not developed on ship after yellow fever had appeared, even when it was impossible to send the sick away from ship in the very beginning of the outbreak; (6) First cases have occurred from the sixth to the twelfth day after leaving port; (7) Transferring a ship's crew from an infected vessel to an uninfected vessel would put a sudden end to the epidemic; (8) The sick transferred from an infected vessel did not necessarily cause new foci; (9) Freezing a ship for an extended period, combined with repeated fumigations under special conditions, did not necessarily kill the morbific agent.

The Result of Mosquito Work in Havana.—Major W. C. Gorgas, U. S. A., chief sanitary officer of Havana during the military occupation, contributed an interesting account of the extirpation of yellow fever and the great reduction of malaria by the campaigns against the Stegomyia fasciata and the Anopheles mosquitos in that city and its vicinity. He organized three sets of mosquito workers: the Stegomyia Brigade, for working in the built-up portions of the city; the Anopheles Brigade, for working in the suburbs and neighboring swamps; and the Yellow-Fever Brigade, for killing mosquitos that might have become infected. The city was divided into inspection districts and every dwelling inspected for breeding places of mosquitos. The first inspection showed nearly every house to have some such place, the last revealed but 187 out of 16,338 houses. The work of the Anopheles Brigade consisted largely of drainage, as the oil treatment could not be effectually applied. The work of the Yellow Fever Brigade was performed in infected houses, which were promptly screened and fumigated with pyrethrum powder. The results of this system of inspection and treatment have been progressive and continuous, until the present condition has been reached.

Original Medical Investigations of the Surgeons of the Imperial Japanese Army.—Surgeon-Captain K. Tamura of the Japanese Army gave an account of the investigations of Surgeon-Major Teuzuki upon the connection between mosquitos and malaria in Japan, including detailed descriptions of three new species of Anopheles—jesoensis, tsuzuki, and foromosænsis I and II, Tsuzuki; these he regards as the transmitters of malaria in Japan. The experiments of Tsuzuki demonstrated that (1) The three species of Anopheles could transmit malaria from man to man; (2) The Plasmodium vivax could develop in the body of Anopheles jesoensis; (3) An infected Anopheles jesoensis could produce malaria by its sting in a healthy person; (4) Laverania malariæ could develop in the bodies of all three species; and (5) The so-called estivo-autumnal fever and tertian fever were found in Japan, but the quartan variety was never seen. The author is also referred to the researches of Surgeon-Major Okada in demonstrating that the poisonous power of the plague bacillus was greatly increased by passing through the bodies of insects. This he followed by a brief account of the suppression of malaria among the troops in Formosa by systematic operations against the mosquitos which infected the island; and closed with a discussion of the hygienic value of paper as a building material in the climate of Japan.

Remarks Suggested by Three Years' Service in Cuba.—Captain John Hamilton Stone presented an interesting survey of various features of note observed during three years' service beginning with the landing at Daiquiri and terminating with the evacuation of Cuba. From experiences at San Juan he was particularly impressed with the value in the order named, of the first-aid packet, drinking water, bandages, splints, brandy, and morphine. His observation of yellow fever confirmed the theory of Reed and Carroll, and he spoke most warmly of the enormous progress of the island in hygiene and health as cause and result, during the American occupation, finally concluding: (1) The great dangers to health, so long ascribed to the tropics, have failed to prove so dreadful when actually tried under favorable conditions and with the help of modern sanitary science; (2) Even the strongest constitution will feel the effects of tropical service after about two years of service; (3) Those with existing cardiac or pulmonary affections should not attempt to combat the physical vicissitudes of the tropics under any circumstances; (4) Those predisposed to tuberculosis should avoid the cities on account of the widespread place infection; (5) The drinking of boiled water and the protection from bites of mosquitos are the most important measures of personal prophylaxis.

Typhoid and Malarial Fevers at Chickamauga in 1898.—Major Edward C. Carter, U. S. A., who organized and commanded the Leiter General Hospital at Chickamauga during the Spanish war, described the work along these lines, which constituted the most important part of the service of that hospital, concluding that (1) The waters of Crawfish spring and of Chickamauga river were contaminated; (2) The contamination was greatest probably in June and the early part of July, 1898, due to storm water; (3) The flies, which were very numerous in the tents during the period of the rains, contaminated the food; (4) While typhoid fever generally exists near Chickamauga Park, it hardly arises to the dignity of an epidemic; (5) Many cases diagnosed as of malarial fever, at Camp Thomas and among the rural population in the vicinity, were cases of typhoid fever with no malarial complications; (6) Malarial fever did exist to some extent at and near the general hospital at Crawfish Springs; (7) Malarial and typhoid fever may coexist in the same patient, but this rarely occurs; (8) A diarrhœa or flux existed, at the hospital at any rate, not connected with typhoid fever.

Pathological Anatomy of Cerebral Concussion.—Professor H. Nimier of the Military Medical School of Val de Grace, the delegate from the French Army, submitted some remarks upon the pathological anatomy of cerebral concussion, based upon the case of a suicide in which the bullet entered at the center of the suprahyoid region and escaped at the vertex, the bony apertures thus produced in the calvarium presenting numerous radiating fissures. In the cerebrum, the bullet destroyed the optic chiasm and part of the right optic layer, perforated the corpus callosum and grooved the internal face of the right hemisphere; the subarachnoid space and the two lateral and fourth ventricles were flooded with blood. Microscopical examination of the cerebral tissues adjacent to the injured tissues was negative, a bullet endowed with a high degree of energy passed through the brain, causing an abundant effusion of blood around and within the cavities of that viscus, without any diffusion of its energy to the nervous tissue, or at least without such diffusion producing any appreciable histological lesion. The author inquired then if we should conclude that the clinical phenomena of cerebral concussion are not dependent upon any anatomical lesion, but perhaps simply the effect of a transient retraction of the neura, with subsequent suppression of nervous contacts.

Effects of the Luger and Colt's Automatic Pistols.—Major Louis A. LaGarde, U. S. A., exhibited a valuable series of skiagraphs showing the effect of automatic pistols which employ smokeless powder and jacketed bullets, and commented particularly upon the penetration and stopping power. While the former is undoubtedly greater, the latter is less except in case of involvement of the diaphyses of a long bone or a vital organ. As a pistol is designed for use at short range, where stopping power is a most important element, the author believed that army surgeons should be very guarded in their recommendation of these weapons in place of the older and more effective revolvers.

Treatment of Venereal Diseases among the Garrison of Vera Cruz.—Colonel Zacarias R. Molina, delegate from the Mexican army, remarked that at Vera Cruz the bubo occupied the first place in order of frequency, followed successively by chancre and chancroid, gonorrhœa, and finally secondary syphilitic manifestations He treated gonorrhœa with the local application of sulphate of zinc, chancre by the employment of the classic black wash, or of salicylic acid in case of an indolent or phagedenic ulcer, returning to the black wash afterward. Suppurating bubo he treated by evacuation and compression with a boric-acid compress. Secondary syphilis he treated with mercury and iodide of potassium combined; the tertiary forms he treated with a saturated solution of iodide of potassium in progressive doses.

Abscess of the Liver.—Lieutenant-Colonel Alfred C. Girard, U. S. A., reported twelve cases of hepatic abscess, eight of which were amœbic and four non-amœbic. From the study of these cases, he concluded: (1) Amœbic abscess of the liver occurred in a very small percentage of the cases of amœbic dysentery observed at the Presidio General Hospital; (2) The recognition of cases of amœbic abscess of the liver is by no means easy, as of the eight cases observed only one presented any clinical symptoms which could not have been referred to the accompanying dysentery; (3) Abscess of the liver may occur without the action of the amœba of dysentery; (4) The symptoms presented in non-amœbic abscess of the liver do not differ materially from those in the amœbic cases, but in all the cases observed at the Presidio Hospital, those of non-amœbic character seemed to have presented symptoms of more severity, as a much larger percentage of these cases were recognized; (5) Operation in well-selected cases of abscess of the liver may be expected to be followed by success where the abscesses are not multiple. As shown in the post-mortem findings of the amœbic abscess cases, operation would have been of no benefit to the patient in those which presented multiple abscess of the liver.

Volvulus of the Small Intestine.—Major George Tully Vaughan exhaustively discussed the subject in the light of sixty-one cases reported in full. Recognizing the difficulty of diagnosis, he considered evident intestinal obstruction ample reason for laparotomy, with a view to completion of the diagnosis and relief of the obstruction. He remarked upon the difficulty of detecting the condition even with the gut exposed. Gangrenous intestine should be removed and an end-to-end anastomosis made. In operating upon hernia, with symptoms of obstruction, the possibility of volvulus in the abdomen should always be borne in mind. No case of strangulated hernia should be reduced without careful inspection, unless there are good reasons for not operating.

The Laws of Physics and Ballistics the True Explanation of the Lodgement and Deflection of the Majority of Modern Small-arm Projectiles, Not the Ricochet Hypothesis.—Major Charles B. Nancrede, U.S.V., held that when the long axis of a projectile, which has lodged, lies at a distinct angle with that of the track of entrance, it has been too readily assumed that it must have had its course altered and its speed retarded by single or repeated contact with extraneous objects during its flight. If, however, such missiles entered in the direction their position of lodgement would indicate, the skin opening would be of a corresponding form, while if they had their course changed after entrance, the skin wounds would be round and of about the same caliber as that of the projectile, or at most be slightly oval in outline, if the missile struck somewhat obliquely. Even when a bullet did enter exactly sideways, making a keyhole opening, there was no certainty that this was due to ricochet, because the ball at the time of impact might have been either revolving around its shorter axis, the "spin" of the ball being nearly spent, or, this latter force being weakened and the ball striking obliquely, this combination of influences might have determined the lateral passage of the projectile.

Immediate Cœliotomy in Penetrating Gunshot Wounds of the Abdomen in War.—Captain CHARLES E. B. FLAGG, U.S.A., presented a paper supplementary to one read last year, in which he replied to some criticisms made at that meeting, fully reviewed the literature of the subject, and concluded that in military surgery, as in civil surgery, immediate exploration of all gunshot wounds of the abdomen and immediate cœliotomy in all cases found to be penetrating were demanded as the only rational treatment and the only treatment calculated to reduce the high mortality in abdominal wounds certainly known to be perforated. No operation and late operation are as direful in their results in military practice as in civil, and it remains for military surgeons to furnish suitable operators and suitable conditions for the treatment of these cases. If civil surgeons could secure a recovery of 66 per cent. by immediate operation upon these cases in hospitals in the homes of the patients, and sometimes with unfavorable surroundings, then military surgeons with their sufficient government supplies and trained nurses should see that their general, base, post, and other stationary hospitals were at all times in such condition as to secure equally favorable results. They should prepare all movable hospitals likewise for these emergencies and, if bound to work under unfavorable conditions occasionally, they should meet them.

Important Actions were taken in making the secretary a permanent officer, establishing the Journal of the Association as a monthly, taking steps toward incorporation by Congress, and moving in the matter of a public service medical school.

Officers and Place of Meeting for 1903.—Boston was selected as the place of meeting for the following year and the following officers were elected: *President*, General Robert A. Blood, Surgeon-General of Massachusetts; *First Vice-President*, Medical Director John C. Wise of the United States Navy; *Second Vice-President*, Surgeon-General Walter Wyman of the United States Public Health Service; *Secretary and Editor*, Major James Evelyn Pilcher of the United States Army; *Treasurer*, Lieutenant Herbert A. Arnold of Pennsylvania.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending July 26, 1902:

	Cases.	Deaths.
Measles	151	9
Diphtheria and croup	229	22
Scarlet fever	133	8
Smallpox	11	3
Varicella	12	..
Tuberculosis	253	135
Typhoid fever	63	17
Cerebrospinal meningitis	..	..

The Transmission and Prevention of Yellow Fever.—Lieutenant-Colonel V. Havard, among other things, says that the hibernation of the mosquito which transmits yellow fever (Stegomyia fasciata), the hibernation of the larvæ in ice, and the wonderful vitality of the eggs which resist the drought of tropical climates as well as the long winters of northern countries, render their extermination almost impossible. There is more hope in the attempt to prevent the mosquito from becoming infected. Unless it has sucked the blood of a yellow-fever patient, it is as harmless as any other mosquito; therefore one of the measures most clearly indicated is to prevent mosquitos from having access to patients by protecting the latter with window-screens and mosquito bars. Any patient thus protected during the infectious stage (first four days), is entirely innocuous. Fumigation is always necessary as soon as the patient can leave his room, in order to destroy any mosquitos which may have bitten him and may still be lingering in the house. We now know that it is impossible for any house to be "infected" with yellow fever, except in the sense that it may harbor infected mosquitos. Fumigation with either sulphur fumes, formaldehyde gas, or the smoke of pyrethrum powder will be all the disinfection required. The disappearance of yellow fever from Havana is due to the incessant battle of the chief sanitary officer and assistants against the Stegomyia fasciata, and the use of effective screens around the patient.—*The Texas Courier-Record of Medicine.*

A Medical Hive.—One of the large office buildings of Chicago is now (above the first floor) entirely given up to the use of doctors and dentists, there being no less than 222 physicians and thirty-six dentists under the one roof. In this respect it probably stands as the most unique building anywhere in the world.—*The Clinical Review.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended July 26, 1902:

SMALLPOX—UNITED STATES.

		CASES.	DEATHS.
California, Sacramento	July 5—12	3	
Illinois, Belleville	July 12—19	4	
Chicago	July 12—19	5	
Joliet	July 1—15	15

A NEW USE FOR THE USELESS APPENDIX, IN THE SURGICAL TREATMENT OF OBSTINATE COLITIS.*

By ROBERT F. WEIR, M.D., HON F.R.C.S. ENG.,
NEW YORK.

PROFESSOR OF SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS.

FOR intractable, ulcerative colitis, whether of amœbic or other origin, surgery has comparatively recently offered its relief. This was at first accomplished by the establishment of an artificial anus in the cæcal region, with the double idea of diverting the the stream of irritating fæces and of also furnishing an opening by which medicated fluids could be employed throughout the whole course of the lower bowel. Keith[1], following a suggestion of White[2] in 1895, resorted to a right inguinal colostomy for a membranous colitis with a good result, and Murray[3] in 1901 reported a case of amœbic dysentery successfully treated by an artificial anus made in the cæcum. Later I twice applied the same procedure, once in the transverse colon and once in the cæcum. In bringing about the cure of an obstinate ulcerative non-amœbic dysentery, others have likewise resorted to this mode of treatment.

But an artificial anus in the right iliac fossa is more incontrollable than when situated on the left side, from the difficulty of a spur formation, and is always a very distressing measure to employ. More lately it has, however, been found that by simply making a fistulous opening in the cæcum, and in this way thoroughly washing out the bowel of its fæces, and then flushing it with a medicated solution, one could accomplish a cure without employing the disgusting artificial anus. This method has been tried by surgeons in Manila and Africa, but Bolton[4] was the first to carry out the plan of Dr. Gibson of St. Luke's Hospital, New York, by making a cæcal fistula in the same way that Kader performs a gastrostomy—that is to say, by placing a rubber catheter of medium size in a small opening made in the bowel and then applying two or three rows of a purse-string suture, so as to invert the adjacent peritoneal coat. This causes a teat-like projection into the lumen of the bowel, which acts later as a valve and prevents leakage to a marked degree. When it so acts, the catheter need only be introduced once or twice a day for the necessary medications. This application of the Kader-Gibson fistula was used by me recently in a man of thirty, who had a long-continued dysentery, non-amœbic in character, with ten to fifteen daily mucopurulent stools, which were occasionally streaked with blood. The patient had contracted the disease in India some two years previously, and had been for a long period under futile medical treatment by mouth and by rectum.

Through the fistula thus made in the cæcum, a tube having been previously passed into the rectum, warm normal salt solution in large quantities was carried from an irrigator (two to three feet elevation into the bowel through the catheter in the fistula, until the rectal outflow became clear. Occasional plugging of the rectal tube was made from time to time, to aid in the complete evacuation of the fæces by a temporary over-distension of the bowel.

The remedies used in irrigation after the cleansing process were a 5 per cent. solution of methyl blue alternated with solution of nitrate of silver 1-5000, or of bismuth ʒ i to the ounce of starch water. Under this management a rapid cure resulted.*

It so happened that on the same day in which the above method of fistula-making was resorted to another case presented itself for treatment in a young man of thirty-one years of age, who had had for nearly three years a persistent diarrhœa, associated lately with profuse dejections of blood more or less unmixed with fæces. He was blanched to a marked degree and his red blood corpuscles had diminished to 2,024,000, and the hæmoglobin to 27½ per cent. His rectal discharges amounted to twenty to twenty-five times daily. When he was first transferred from the medical side of the Roosevelt Hospital to the surgical division, under my charge, I detected on my initial examination of the rectum a broad fibrous polyp just above the prostate, which I thought might be the cause of the hemorrhage, this was removed, but the bleeding continued. There was no ulceration to be seen by the proctoscope, though tenderness and thickening of the intestine were detected in the sigmoid region. As medical means had failed utterly, I made first, in April last, an exploratory incision above the umbilicus, and found there, as well as above and below this point, much thickening and congestion externally of the colon as far as it could be felt and seen. It was determined, as no special tumor was felt within reach, to resort to a cæcal fistula, as had been employed in the case above referred to, whereupon the intermuscular separation of the abdominal wall was employed to carry this out. As the cæcum was exposed the appendix rose so suggestively into view that I determined to employ it to make the desired fistula. It was accordingly fastened to the skin, and the rest of the wound then closed. But as my knowledge of the capacity of the appendical junction with the cæcum was mainly obtained from the abnormal conditions that exists in appendicitis, I was not willing to leave this question untested, so I deemed it wiser after the appendix had been duly sutured in the skin wound to open its tip and pass into its lumen a No. 12 English rubber catheter which entered freely into the cæcum. Then this opened tip was closed beyond the skin level by a temporary ligature, to prevent leakage and the prescribed dressings applied. The next day this ligature was removed, and two days later the irrigation treatment was resorted to with the most satisfactory results. The contrast between the two methods of forming a fistula was very marked. In the first one, by the Gibson-Kader method, more time was occupied in its performance, and there occurred a mishap which, though not common, is yet possible to the most careful surgeon, to wit, the slipping out of the introduced tube, from an unguarded movement of the assistant, and the consequent escape of a small amount of fecal liquid. This took place, and though the infection was promptly checked and remedied by careful irrigation, the next day there was a good deal of tenderness in the right iliac fossa and some anxiety was felt lest there might be serious trouble arising therefrom. This, however, promptly passed off, but it evidenced a risk that could have been avoided by utilizing the appendical tube. Whether in other cases it would be required that the appendix should be opened at the time of the operation, to determine its patency, I cannot yet say, but even if it is then deemed best, its temporary closure by a ligature ensures against infection. The outcome of this experimental case has been a most happy one, not only as to a progress toward a cure by virtue of the irrigations for cleansing and medicating the bowel, but also from the fact that owing to the normal muscularity of the appendical wall, a certain amount of restriction therefrom has prevented any leakage from the, so to speak, normal fistula, which, furthermore, has not had the same tendency to close as had the walls of the peritoneally-formed Kader fistula.

*Read at the meeting of the American Medical Association, Section of Surgery and Anatomy, June 11, 1902.

*For amœbic dysentery quinine solutions have much repute in the Philippine hospitals.

At this time, June 11, two months after the treatment began by the fistula, the patient's condition has markedly improved. The blood has disappeared from his stools, which have been reduced from twenty-four to five or six daily. His blood count has now reached 3,600,000, hæmoglobin 60½ per cent., and his progress is steadily toward a cure, and he is steadily gaining weight and strength.

In this case the nitrate of silver injections, two grains to the ounce of water, alternated with bismuth, gave the most relief.

When the normal defecation is reached one need only plunge the point of a Paquelin cautery into the lumen of the fistula to bring about the destruction of the mucous membranes, and the subsequent obliteration of its tube by cicatrization, or if its anchorage to the abdominal wall be considered inadvisable, the usual operation for the removal of the appendix, as in the "interval" operation, can be done.

Hæmatoma of the Sheath of the Radial Artery.—E. Juvara describes this occurrence in three cases, due respectively to a blow during gymnastic exercises, a blow against the edge of a door, and a blow from a cane received while playing ball. Pain is followed by the appearance of a small tumor on the postero-external surface of the wrist. This is circumscribed, well-defined, smooth, regular, spherical, soft, and fluctuating. Under pressure it disappears, but a cylindrical projection several centimeters in length appears toward the root of the thumb, where it ends in a culdesac. This is the sheath of the extensor longus pollicis, the cavity of which is filled with the blood pushed out of the sheath of the radial artery. The rational treatment consists in aseptic puncture and aspiration, followed by the application of collodion to the small wound, and a dressing consisting of a little roll of cotton batting, held in place by a flannel bandage. The hand is placed in a sling, and kept quiet for about six day when the dressing is removed and massage is given two or three times.—*Revue de Chirurgie.*

THE MEDICOLEGAL VALUE OF THE RONTGEN RAYS.*

By CARL BECK, M.D.,
NEW YORK.

PROFESSOR OF SURGERY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, VISITING SURGEON TO ST. MARK'S HOSPITAL AND TO THE GERMAN POLIKLINIK, CONSULTING SURGEON TO THE SHELTERING GUARDIAN SOCIETY ORPHAN ASYLUM, FELLOW OF THE GERMAN SURGICAL SOCIETY (BERLIN).

WITHIN the two years which have elapsed since I had the honor of presenting to this society a paper on "Errors Caused by the False Interpretations of the Röntgen Rays" (see MEDICAL RECORD, August 25, 1900), great strides have been made in this new and fascinating field. Accurate knowledge has taken the place of ignorance and doubt, and painful manipulations are no longer a necessity for diagnostic purposes.

Even the most skilful experts in fractures have ceased to deny that there is an enormous number of bone injuries, which, in former years, could not be properly recognized, the general symptoms being either obscure or veiled by the swelling of the surrounding tissues. The mistakes made in differentiating fractures from dislocations, contusions, distortions, or tumefactions were innumerable; but they could be proven as such only under extraordinary circumstances. The Röntgen rays have brought about a revolution. They show the conditions as they are, and are impolite enough to do this without the slightest regard for great authorities. No wonder that such brusque information was received with a feeling of uneasiness, often by the very men who should have been but too glad to learn of their diagnostic errors, in order to correct them. As you know, the errors made in the interpretation of skiagraphs, of which so much was then heard, supplied a favorite argument in defense of their procrastination.

We have learned now that our misinterpretations were caused by insufficient anatomical knowledge, as well as by technical shortcomings with which the rays had nothing to do. Officious friends, inconsiderate and malicious confrères, and shyster lawyers heralded and misapplied the great discovery, and succeeded for a while in discrediting it even among those members of the medical profession who had begun to appreciate its great value. But these times have passed. The Röntgen rays no longer need a gladiator in the medical arena, but their recognition in the courts leaves much to be desired.

Since it is accepted by the medical profession that a plate, which is accurately made by a physician specially trained in skiagraphy, and interpreted by an expert, gives most valuable information which cannot be obtained otherwise, the Court should regard it its duty to acknowledge this fact and avail itself of it in the interest of justice. Especially the judge of the modern era of humanity in contrast to the obsolete representative of the old dogma "*Fiat justitia, pereat mundus!*" must see a valuable ally in this most wonderful discovery of the last century.

What a triumph for suffering mankind are the numerous cases in which veteran soldiers, contemptuously treated as malingerers before the courts, can now show the skiagraphic proof of the presence of foreign bodies. A patient whose body harbors a bullet, has, indeed, a very good reason to complain. The number of patients who submitted to unnecessary surgical operations because foreign bodies were suspected, but not found, and the still larger number of those who were not advised to submit to operations, although they were needed on account of the non-suspected presence of foreign bodies, is legion.

---

* Read before the Society of Medical Jurisprudence, May 12, 1902.

Long before the Röntgen era, when I was a young assistant, a woman was referred to me for an obscure swelling along the first phalanx of the left index finger. The anamnesis revealed that the swelling had come on slowly after she had wounded herself with a needle. She reported that the needle was broken, but that the fragment was pulled out by herself. There was but little pain, but much functional disturbance. The impression prevailed that there was an inflammatory process caused by an infected needle. Later, when fomentations and immobilization were of no avail, rheumatism, osteitis, and then tuberculosis was suspected, and, besides the application of tinct. iodi, internal medicines were administered. No improvement being obtained, I studied all the textbooks available for information, but my scientific thirst was not quenched. My old routined chief, whose advice I then sought, suggested that I should make an exploratory incision, which I did. How great was my surprise when I found a small needle-fragment buried alongside the phalanx! I have never forgotten the feeling of humiliation which overcame me then in the presence of the patient. But I believe that I do not stand alone in this experience. *Solamen miseris, socios habuisse malorum!* To-day a simple glance with the fluoroscope would at once have pressed the extraction-forceps into my hands.

This experience also reminds me of the case of a man (demonstrated by me before the Surgical Section of the New York Academy of Medicine) who carried a thick glass splinter underneath his zygoma for thirty-eight years, experiencing but little pain, until, shortly before Röntgen's discovery, a swelling below his eye led him to seek medical care. The swelling was regarded as a malignant growth. He lived in a country town, and was advised to go to New York and have his superior maxilla resected. On making an incision I found the glass splinter, and when the patient saw it, he remembered that when a boy he was wounded in his face by the explosion of a glass bottle containing gunpowder. The facial wound had healed without reaction. In this case, also, the Röntgen rays would have made the nature of the growth clear at once.

An odd pendant to the needle case is illustrated by the skiagraph of the foot of a dwarf, which I made two years ago. For about two years the hero of the tragic comedy had been a round-trip patient in most of the reputed clinics of New York City. He showed a slight swelling at the outer aspect of his foot, which was diagnosticated as periosteitis, osteitis, osteoma, osteosarcoma, beginning tuberculosis, rheumatism, arthritis, syphilitic proliferation or exostosis, badly united fracture, etc. Later on amputation, as well as exploratory incision, was advised. After having suffered for more than two years, he was ready now to submit to anything which would relieve him from the pain he suffered while walking. I was unable to make a diagnosis with the usual methods, but the Röntgen rays cleared up the situation at once, showing a needle in the sole of his foot. When the patient was informed of this fact, he remembered that about two years ago, while sleeping on a lounge, he fell on the carpeted floor and noticed a sharp pain in his foot, which he explained by the fall itself. He had undoubtedly fallen on a needle sticking out of the floor, and by walking he had shifted it up into the joint, from which I removed it under considerable technical difficulties. It is needless to say that his "rheumatism" disappeared at once.

Much more serious, from the standpoint of humanity, is the following case, reported by Dr. L. Passower, Riga (*Aerztliche Sachverstaendigen-Zeitung*, No. 15, 1901). In November, 1897, a young farmer, suffering from a swelling of his foot, was admitted to the surgical division of the army hospital of Riga (Russia) for observation. Being a recruit, he was expected to serve his military term. But a year before a mass, weighing thirty-five pounds, had fallen on his leg, causing an injury which compelled him to stay in bed for three months. It was reported that during that time the foot had appeared much swollen and ecchymotic. When admitted to the service of Dr. Passower at the military hospital he was limping and complained of a continuous pain in his foot.

He was assigned a bed among old soldiers, who were requested to watch him closely, as he was suspected to be a malingerer. Three days after admission Dr. Passower received an anonymous letter, signed by "a friend of the recruit," which contained the information that the patient had produced the swelling himself, constricting his thigh and injecting medicamentous substances underneath his skin. Dr. Passower stated that he did not pay much attentien to this communication, but deemed it his duty to order a still closer watch by adding a subaltern medical officer (Feldscheer) and a professional nurse to his outpost. Besides this, he as well as his assistants, visited the poor victim repeatedly and unexpectedly during night time, but were never able to discover anything wrong. After two weeks the œdema had subsided, but the tarsus still remained thickened, motion of the ankle-joint also remaining painful. Especially pressure on the scaphoid bone produced intense pain. As soon as the bandages were removed the œdema returned. So Dr. Passower came to the conclusion that the patient suffered from a chronic inflammatory process of his tarsal bones, produced by an injury. The possibility of a fracture of one of the bones was also duly considered.

After four weeks' observation he was presented to the medical board of the hospital, which suggested that he should be exempt from military service for a year. It was expected that the swelling would gradually disappear if the patient could enjoy rest at home and regular treatment. But the military commission of Riga did not accept this suggestion, because one of its physicians insisted upon the theory of the artificial origin of the swelling. So the unfortunate candidate was sent to the City Hospital of Riga, where, after a second examination, he was accused of having injured himself by constriction and puncture in order to get rid of his military obligations. So he was delivered to the public prosecutor, but set free after a long trial, and especially through the efforts of Dr. Passower.

A few weeks later he was again arrested and sentenced to three months' solitary imprisonment for self-mutilation. Now Dr. Passower recommended transferring the criminal to the clinic of Professor W. W. Koch in Doypat, in order to obtain a skiagraph. This was at last permitted, and so Professor Koch had a chance to ascertain that there was a fracture of the astragalus, which had caused sinking of the sustentaculum of the astragalus. The patient appealed to a higher court, which dismissed the previous sentence. At the end of February, 1900, the government referred him back to the military hospital in Riga, where he was skiagraphed. (It seems that a Röntgen apparatus was not obtained in this university town until then.) The evidence in favor of the "criminal" was too overwhelming, and so he was declared unfit for the military service.

Thus an honorable man was virtually imprisoned during a period of three years. If a skiagraph had been taken at the time of his admission at the military hospital (fully two years after the publication of Röntgen's discovery), the whole procedure of ignorance and malicious arrogance would not have been set in motion, and the psychical torture of another poor individual would have been rendered impossible. In the face of the skiagraphic illustration of the fracture of the most important bone of the foot-skeleton, no judge and no jury would have dared to dispute the claims of the patient.

The counterpart is represented by a case which I reported to this society two years ago, and which I desire to review briefly, since at the same time it shows how important for proper interpretation is the knowledge of minute anatomical details. It has occurred to me as well as to others that the normal os intermedium cruris (os trigonum tarsi) has, after a single exposure, been taken for a fragment severed from the astragalus. In my case a fracture of the fibula was present, but the first skiagraph suggested the presence of a tibial fragment also. But this was cleared up by a subsequent exposure in a different projection-plane. (See Medical Record, August 25, 1900.) The os intermedium cruris is a typical part of the tarsus of all mammalia, and its frequency is estimated at from 7 to 8 per cent.

The practical significance of this bone is evident from a case described by Wilmans of Hamburg. A laborer claimed that he was injured by an iron bar on January 20, 1897, but was able to work during the whole day. On the following day he called on Dr. Wilmans, complaining of intense pain at his internal malleolus. He limped and asserted his inability to work. Wilmans found a slight swelling below the right internal malleolus. Ecchymosis of the skin being absent, the swelling was attributed to the presence of a considerable degree of talipes, from which the laborer suffered at the same time. The leg was elevated and fomentations were applied for several days. The patient still complaining of great pain, it was decided to transfer him to a hospital for observation. When discharged, after several weeks of treatment, the laborer made an effort to resume work, but at once declared that he was unable to keep it up. He was therefore admitted to another hospital, where he repeated this manœuvre several times during a period of six months. Finally, he claimed damages for having been crippled by the injury sustained on January 20, 1897, but in view of the negative objective condition found by Dr. Wilmans, the society decided not to grant any claim. The consequence was that the man was transferred to the surgical division of a third hospital for further observation. There he complained that he had continuous pains below the right external malleolus, even while in the recumbent position. The pain increased during walking or sitting. Stepping on the right heel he also declared to be impossible. By distracting his attention, however, it was noticed that he could stand well on his heel, and he would doubtless have been declared a malingerer had not the Röntgen rays come to his rescue, at least temporarily. A skiagraph showed a bone-fragment at the junction of the astragalus with the posterior surface of the calcaneum. On the strength of this skiagraphic "proof" Dr. Wilmans, although still mistrusting, was forced to modify his original opinion and certified that the patient suffered from "fracture of the astragalus, in consequence of which he was damaged for life." The laborer therefore received an annuity of 30 per cent., in proportion to the estimated curtailing of his wages. Soon afterward the laborer was seen by Dr. Wilmans carrying a heavy load without any apparent pain, while formerly he had claimed to be unable to walk without a cane or crutch. Now Dr. Wilmans insisted upon a second irradiation, this time also skiagraphing the uninjured left foot. The skiagraph showed the "severed bone-fragment," which had first been regarded as a sesamoid of the musculus flexor longus hallucis, but which now was recognized as a normal os intermedium cruris. The society, of course, refused the annuity, and the German supreme assurance court, to which the man had appealed, not only sustained the verdict of the society, but also decided that the laborer must return the annuity which he had unjustifiably enjoyed for eighteen months.

In this case the Röntgen rays were very near becoming the contrary of what they are expected to be, namely, a protector of dishonesty. But the fault would have lain with the insufficient anatomical knowledge and not with the rays themselves, which reproduced the condition exactly as it was. The repetition of such cases, however, is highly improbable.

A complicated medicolegal question will arise when chronic diseases develop after an injury. Osteitis, arthritis deformans, and even malignant growths are not infrequently observed in this connection. If such injuries are sustained in factories, a suit for negligence is generally brought against the owner. The amount of damages, of course, depends largely upon the duration of the healing process and the degree of functional disturbance. This will vary greatly—as from a case of simple fracture, which may be accurately united in a few weeks, to an injury followed by the development of a malignant growth, which will finally cause the death of the patient.

The skiagraph, for instance, which I present to you illustrates the case of a laborer fifty years old, who sustained an injury of his elbow eleven years ago. He reported that recovery took place after months, and that the elbow had remained stiff ever since. During the last few years inflammatory signs had manifested themselves which were regarded as rheumatic. No other joints were involved. Since then he also had repeated attacks of pain in the elbow-joint.

When I first examined the patient I found the elbow very much thickened and fixed in a sharp angle. Pressure below the external condyle caused intense pain. Crepitus, so often found in old arthritic processes, could not be produced in this instance, as the joint permitted no motion at all. There were no indications of tuberculosis, syphilis, or gonorrhœa.

The skiagraph revealed the presence of malunion (side ways displacement) of the coronoid process of the ulna. This, probably, had given the first impetus for the development of the arthritis deformans, which is especially well marked in the external condyle of the humerus. The left condyle showed synostosis with the olecranon. Removal of the projecting fragment by the chisel, separation of adhesions, and the partial resection of the external condyle, the seat of predilection for the acute attacks were advised as therapeutic means.

It was promised the laborer, who sustained his fracture in a factory, and who did not show any signs of ill health before, that he could use his arm again a few weeks after the accident. After ten weeks he was able to resume light work; then the swelling became gradually worse, and the diagnosis of arthritis was made. He has remained a cripple ever since, and his wages were cut down considerably. He might have claimed damages, but in view of the presence of the arthritis he realized the difficulty to prove that there was a fracture originally. The Röntgen rays would have furnished this proof for him.

The development of malignant growths after an injury is illustrated by another skiagraph which shows the faint outlines of bone-shell in the soft myelosarcoma of a woman of twenty-eight years, who had fallen on her hand in dorsal flexion. The swelling resulting from it gave the impression that a fracture of the carpal end of the radius was sustained. Three months after the injury, when I first saw the patient, I noticed a small deformity, just as it is observed in badly united fracture of the carpal end of the radius; but the consistency of the epiphyseal end was soft. The skiagraph failed to show the evidence of bone-tissue, only one small remnant being left at the outer aspect of the radius. Resection was advised; but before the patient submitted to it another month elapsed, during which time the neoplasm had grown to twice its size. The result was reported fair eight months after the operation. But the chances of a permanent recovery are poor. (See "The Differentiation between Inflammatory Processes and Neoplasms," *Annals of Surgery*, December, 1901.)

It is not always possible to show the evidence of a fracture as long as twelve years after its occurrence, as in the case of the laborer described, in which the displacement proved that there was fracture of the coronoid process of the ulna. The older the fracture, the less the fracture-line will appear. In case of the entire absence of displacement it is only a very distinct skiagraph that shows the line clearly. It is natural that in such cases there is no skiagraphic evidence after recovery—that is, in from four to ten weeks, according to the type of the fracture. Should a jury in such an event doubt that there has been a fracture, a skiagraph taken after such a period will show a negative result, although there surely was a fracture. At my last demonstration I showed you a boy whose fracture of the femur could not be shown by a very distinct skiagraph taken two months after the injury, because there was blameless union. Had I not skiagraphed the thigh shortly after the injury, no evidence of the fracture could have been obtained subsequently.

In the case of a girl who sustained a fissure of the head of the radius followed by considerable functional disturbances, the blameless skiagraph, taken four weeks after the accident, showed ideal union, so that no fissure-line could be recognized. This also proves how quickly the evidence of the presence of a fissure becomes lost if there be perfect approximation. (Case presented to the surgical section of the Academy of Medicine, January 14, 1901; see *Annals of Surgery*, April, 1901.)

This experience suggests that a mediocre or even indistinct plate should never be admitted in court. It has repeatedly occurred to me that I was not able to discover a fissure, or fracture-line in a mediocre skiagraph, which appeared well marked in a blameless one. Such facts explain very well why some surgeons have disputed the reliability of other fellow-observers. Dr. A, for instance, insisting, and properly, upon his own diagnosis, while Dr. B, with his poor skiagraph, ridicules Dr. A's imagination, sneeringly asserting that he could find no fissure-line. Of course, Dr. B's opinion is thoroughly honest, but absolutely erroneous, nevertheless. It should also be considered that during the first days of the injury the presence of a fissure is easier overlooked than later when callus-formation begins.

But that even in a fairly good skiagraph a fracture, followed by no displacement, can be overlooked, is illustrated by the patient whom I present to you, who sustained a fracture of the middle of the radius three weeks ago, a heavy brick having fallen on his outstretched arm. He had great pain at the seat of the fracture, his hand was slightly swollen, and there was disturbance of function. Crepitus could not be elicited. A fluoroscopic examination made by myself, as well as by a number of physicians, revealed nothing abnormal. A fairly good skiagraph made at the time proved negative. Another one, taken in the opposite direction, gave the same result. But my suspicion that a fracture was present was so strong that I made a third exposure, this time long enough to bring out the bone-texture, the result of which was the faint representation of an oblique fracture-line at the point of tenderness. A fourth skiagraph, taken from the extensor-side, revealed the fracture-line still more distinctly.

When in this case I was unable to represent the fracture at first, some of the physicians present suggested that this was a proof of the integrity of the bones and that the soft tissues, perhaps a nerve, were injured. But, as a rule, injuries of this kind are only found in nerves, when there is a synchronous injury of the bones, the fragments of which generally produce the trauma of the soft tissues. In a case of this kind a difference of opinion between experts may happen in court, and the patient may become the victim of an imperfect technic.

A counterpart to this case is the one of a boy who was under my treatment after extirpation of his cervical glands, and who sustained a contusion of the forearm, while I happened to be absent from the city. So he was referred to a brother physician, who was supposed to be an expert in Röntgen science. Relying entirely upon the fluoroscopic screen, he claimed to have seen the fracture line and declared a photograph to be unnecessary. A plaster-of-paris dressing, extending over wrist and elbow, was applied in consequence. A few days later, when the patient was referred back to me, I made a fluoroscopic examination of the arm, and as I could see no fracture line, I took a skiagraph through the plaster-of-paris dressing. No evidence of fracture being found, I removed the plaster-of-paris dressing, although the bones presented themselves very distinctly. This third skiagraph proved that there was absolutely no fracture, a fact which was corroborated by the perfect function of the arm.

These two cases afford further support for the demand that only blameless skiagraphs should be admitted as evidence in court.

While we can readily see that a skiagraph furnishes the most convincing proof of the extent of the bone injuries, it does not show the injuries of the soft tissues, at least not directly. Therefore a skiagraph alone is not conclusive for the purpose of estimating the degree of functional disability. A non-medical skiagrapher will, therefore, never be able to give expert testimony in any case of injury. If there is only one skiagraph taken the injury may appear at its worst, and *vice versa*. So a skiagraph may show a considerable degree of bony deformity, and still the function may be but little disturbed. Even our best results show, especially when displacement of the fragments or other unfortunate complications were present, no ideal union, and still the function may be fair. An unscrupulous patient, who secures possession of a skiagraph of his own case, which shows considerable deformity, may strongly appeal to a jury on the strength of his deformity, especially if he succeeds in simulating great disturbance of function. On the other hand, there may be but little evidence of bone injury on the skiagraph, but there may be severe impairment of function on account of the injury of the soft tissues (circulatory, trophic or inflammatory disturbances), which can be produced only faintly, if at all. Thus we see that in a given case the skiagraph must be considered in connection with all the clinical symptoms, and this can, of course, only be done by an experienced medical expert. As alluded to, a thorough anatomical knowledge is required. But it is also necessary to know the different modes of delineation in various projection planes. At my last demonstration (see also *New York Medical Journal*, January 6, 1900) I reported the history of a boy, whose fracture of the lower end of the tibia was not shown in the anteroposterior position, but appeared very distinctly in the lateral projection plane. If the case was brought before a jury, an expert might there, on the strength of the first skiagraph taken in the anterior-posterior projection, have testified, in good faith, that there was no fracture. With our new improved technic, however, even in this position, a faint indication of the fracture-line is generally shown.

Similar cases are reported by me in the *Annals of Surgery*, August, 1901, and in *Die Roentgenstrahlen in der Chirurgie*, Seitz und Schauer, Munich. The skiagraphs, for instance, which I show you here, illustrate a case of osteoepiphyseal separation of the radius in a lad of sixteen years, who had fallen from a stone stairway. By looking at the first skiagraph only, the impression of normal, non-ossified epiphyseal ends must necessarily prevail. The other skiagraph, taken with the ulnar margin of the hand slightly lifted, shows the presence of the fracture line beyond doubt. The third skiagraph, taken in the lateral position, markedly illustrates the displacement of the fragments.

These cases are another proof of the absolute need, as stated on previous occasions, of taking at least two exposures in different positions in all fracture cases. In joint-injuries it is often necessary to make a skiagraph of the healthy joint of the opposite side at the same time, in the same position, and in the same projection. Sometimes it is also advisable to compare a normal skeleton with a skiagraph, since some pathological conditions, like rachitis, syphilis, etc., influence the outlines of the bones and may deceptively be supposed to represent a portion of an injury. The fact that in children the epiphyseal tissues are not sufficiently ossified to produce a shadow on the plate has caused many, but unjustifiable errors at the early Röntgen era.

In many fractures the destruction is so extensive that a good result could not be expected under any circumstances. Then the patient may be tempted not only to claim damages from his employer, but also from his physician. In such a case a skiagraph, taken as early after the accident as possible, will be the best protection for the physician. It would be a document showing that the physician knew well the serious nature of the injury. The skiagraph I present to you illustrates a multiple fracture of the elbow. Splinters of bone are scattered and are shown imbedded in the soft tissues. Only a fool would, on the strength of this skiagraph, have expected the surgeon to restore the lower end of the humerus, which was almost completely shattered, to a normal condition.

Or if a deformity is caused by excessive callus-formation, the skiagraph will be the surgeon's advocate. In one of my cases considerable deformity at the wrist was present, which caused disturbance of function. The skiagraph showed the fragments in splendid apposition, proving that the deformity was produced by excessive callus-formation, for which, of course, nobody can be made responsible. The patient who accused his physician of malpractice could, when he saw the skiagraph, be easily convinced by me that he had done great injustice to his physician.

Another important medicolegal question arises in another case which I will mention. A girl of twenty-three years fell downstairs on March 5, 1902. The family physician found considerable deformity, which he corrected to a great extent. When the swelling surrounding the whole elbow did not subside after a week, he referred the patient to me. Before I made a Röntgen examination I had the impression that there was a fracture of the external condyle. But the skiagraph revealed the presence of a fracture of the head of the radius, associated with considerable displacement, infraction of the external and fracture of the internal epicondyle, the latter injuries without displacement. Since I could locate the displaced radial fragment so well by the rays, I assumed that I could now also succeed in reducing it. But I was not able to palpate it. A fairly large number of physicians tried the same, but, with the exception of a young practitioner, none could feel it. So I marked the position of the fragment as my anatomical knowledge indicated it and pressed inwardly. Now I applied a fenestrated plaster-of-paris dressing, through which I took the skiagraph. This showed most impolitely that I had not only failed in my efforts of reposition, but had even made it worse. Now I tried to reduce it in the extended position, as it is indicated in the third skiagraph, and there I could press the fragment nearer to its normal position. This encouraged me to make a fourth attempt in the same position of the arm, and this time I succeeded fully, as the skiagraph shows. As you see the result is a good one.

In this case a diagnosis without the Röntgen rays was simply impossible, and without the diagnosis the patient would surely be crippled. It was not until weeks had passed and the swelling had subsided that I was able to grasp the radial fragment, which is of such great importance in view of its joint surface. Would the court have the right to censure the physician if he had not advised skiagraphy? Could he be accused of professional negligence? If litigation ensued, would the other party have had the right from the beginning to insist that a skiagraph be taken? And if I had not succeeded in reducing the fragment, would I have been criticized? I leave these questions to our learned lawyer friends. What, I may ask further, does secure the identity of the patient who is skiagraphed? Is it sufficient that he signs his name on the envelope of the plate, with a pencil containing impermeable substances, so that his signature is photographed together with the limb, or is it necessary to have a witness present, or both?

This brings us in touch with another question, which is a burning one in the full sense of the word: Is the physician responsible for an injury-burn, caused by the peculiar influence of the rays, if they are used for diagnostic purposes? It seems that in some individuals an idiosyncrasy exists which can be compared with the so-called iodoform idiosyncrasy. This susceptibility cannot be recognized except after the burn has established itself, when, in other words it will be too late for prophylaxis. All we know is that blonde individuals are more susceptible than others. There are no means at all which protect the body from this except at the expense of a thorough examination. Since the time of exposure has, thanks to our improved apparatus, been considerably diminished, the danger of burning the patient is, however, extremely small.

As the Röntgen rays have also shown therapeutic properties, this question has reached a new phase. In order to exert a curative influence, frequent and powerful exposures are required, and consequently the chances of burning the patient are not small. In some instances, especially in non-malignant skin diseases, a protection can be obtained by lead masks. But if malignant growths, like cancer or sarcoma, are treated, too much irradiation can hardly be done. In view of the fact that the cancer cells are not confined to the growth itself, but are also found in the adjacent tissues, it is necessary to irradiate as large an area as possible. Where ulcerations exist already, as it often happens in carcinoma, and where new ulcerations, as well as inflammatory processes may originate every day, an unscrupulous patient may claim that they were caused by the injudicious use of the rays. How can the physician protect himself against such allegations? Is it necessary to have the patient sign an agreement stating that the risks of the Röntgen theraphy were explained to him? Or are further ceremonies required?

You can readily see that numerous medicolegal questions have turned up with this wonderful discovery, and I know of no body that is more fit to answer them than this society.

A CASE OF MULTIPLE PERSONALITY.*

By J. ALLEN GILBERT, Ph D., M.D.,
PORTLAND, ORE.

Mr. X. was admitted to St. Vincent's Hospital to the U. S. Marine ward under the care of Dr. J. O. Cobb, February 20, 1902. After apparent recovery from the injury for which he was admitted he continued to act queerly for over a month, manifesting symptoms which could not be accounted for by mere concussion of brain, as indicated by the history of the accident and symptoms on admission. On April 1 I was asked to see him and from then until May 16 the following history was taken:

Family History.—Father living and well. Not much known of him or other relatives. Mother died when three years old. Cause unknown. One brother living. None dead.

Personal History. — Age, twenty-two years. Never ill until the present accident. Venereals denied. No liquor or drug habit.

Physical Examination.—Well nourished. Height, 5 feet, 10¾ inches; weight 180 pounds. Dark hair. Line of the hair runs to a point in center of the forehead. Eyebrows meet and extend down over the nose. No wounds of the scalp. Painful spot one-half inch in diameter on left occipital protuberance, one inch from the median line. Broad face. Eyes normal in reflexes and movements. Catarrh of long standing in right ear. Left ear normal. Other senses normal. No paralyses. Pulse, 94; temperature, 98.6; respiration, 19. Chest measurement on exhalation, 38 in.; on inhalation, 42½ inches. Lungs, liver, spleen, and heart normal. Deep and superficial reflexes normal. No anæsthetic areas. Right inguinal hernia retained by a truss. Urine normal except for excess of phosphates. Blood count, reds, 5,655,000. Whites, 7,650. Percentage of whites: Polymorpho-nuclear-neutrophile, 54 per cent., mononuclear leucocytes, 45 per cent.; large lymphocytes, .2 per cent.; eosinophiles, 1 per cent.

History of Present Illness.—Fell from a barge onto a log in the water eight to ten feet below. Struck head on left occipital protuberance. Stunned for a short time. Rallied and crawled up on the logs. Head burned like fire all over. Walked like a drunken man. Very watery and copious movement of the bowels, accompanied by severe vomiting, fifteen or twenty minutes after the fall. He was taken ashore and started to town. Walked part way; on street car the balance of the way. After boarding the car and riding a short distance nothing more was remembered till in the hospital about three weeks later. When taken by the ambulance he was apparently rational, but exhausted. On waking in the morning he would chase rats in the bed. On second day after entrance to the hospital he rose from bed, said he felt all right, and asked to be discharged. He was apparently well, and the discharge was granted. His friends noticed he was not normal and brought him back the same day. He left the hospital thus three times, apparently normal, but he remembers going out only the last time. All events previous to that are a blank since boarding a street car after the barge accident. During his stay in the hospital in the early part of his sickness he would have spells of semi-delirium. Peevish and troublesome at times, generally quiet and orderly. There were gathered a few facts in regard to things he did and where he went during his first two trips out of the hospital, but he could not recall them after they were related to him. Throwing the head backward caused things to turn black before his eyes. Unusual movements affected his eyes. At first almost continuous pain over the eyes and in the head. Extremely nervous at times; so much so that pricking his ear for blood "set him on nettles."

The patient's life being largely a blank since the accident, and inasmuch as he had unwittingly collected and signed a receipt for his wages, and not knowing what else of importance he may have done, with the patient's consent I hypnotized him to ascertain his actions during the period which was a blank to him. In hypnotizing him it was impossible to get control of his eyes until after the arms and hands were under control. Fixation with the eyes made them hurt, and even with the eyes shut, manipulation of them gave flashes of light. This was likely due to the blow from the fall on the visual area of the brain. It was also impossible to hypnotize him while lying down, because of dizziness and flashes of light. Hypnosis was induced slowly but successfully in about one-half hour. While in the hypnotic state, in muffled voice, in response to questions, he gave in detail his life during the time subsequent to the accident. Subsequent investigation verified his statements in every detail so far as memory could serve, for no notes were taken inasmuch as multiple, or even double personality was not suspected at this time. To close the hypnosis I suggested that he would awake when I counted five, having previously suggested that at the end of the counting he would wake and feel perfectly well in every regard. To our surprise he awoke with a start, the very picture of fright, trembled like a leaf, demanded where he was, knew neither Dr. Cobb nor myself and, all in all, was a picture of mental distress. The patient was quieted, and on questioning him it developed that we had before us a case of double personality. He gave his age as eighteen years, never had been in Portland, spoke of events which he said took place "yesterday," and on questioning it was found that he thought it was September, 1898. All time and events since then were an utter blank. Subsequent developments proved that this date was 1899 instead of 1898. Previous to 1899 he had a lapse into another personality which lasted about a year. Hence the dropping of a year. Mere mistake in dates, however, may account for the mistake without reference to the lapse previous. He said that "yesterday" (*i. e.* Friday, Sept. 1898.) he had a fight with his father in Glenrock, Wyo., and on being told that he was in Portland he asked whether it was Portland, Ore., or Portland, Me. The patient being somewhat disturbed in mind he was put in the ward to quiet down and get acquainted with his new surroundings. He knew none of his companions in the ward and had to be shown his bed, hat, and belongings in general—in short, he was a stranger in a strange land. The case throughout presented many queer and interesting data, which must, of necessity, be omitted in this presentation of it.

---

*The present article can give only the major facts of the case. A full account, presenting the detailed history and development of the case, may possibly appear later in a separate publication.

At 4 P.M. on the same day (April 2) the following history was taken from him, told in a perfectly clear-headed and intelligent way:

Born December 15, 1878 or '79—not sure which. Born at Nemeha City, Neb. Mother died when three years old. One brother, one half-sister, one stepsister, father, two grandfathers, two grandmothers, and a stepmother, giving their names and addresses. Moved to Nebraska City shortly after birth and then to St. Paul, Neb. Ran away from home when fourteen years old and went to relatives on mother's side. Omitting details in this writing, he went to Bloomington, Omaha, Ashland, and finally to Lincoln, Neb., and enlisted for the war with Spain. Went as far as Chickamauga and took sick with a fever of some kind. Cannot remember how he got back to Nebraska, but the first he could remember he was working in Oxford, Neb. During this lapse, I learned subsequently, he had been hunted for desertion—the desertion, however, not being true desertion, for he changed personalities in camp and left, not knowing that he belonged to the army. Omitting details again, he went to Oxford, Mascot, Holdredge, and Glenrock. While here his father and stepmother quarreled, and in his attempt to interfere he and his father quarreled. During the quarrel, it seemed to him, his father hit him on the head with something. That was the last he could remember until he woke up here in Portland. There was no headache in this personality. Perfectly well in every way. Refused to take medicine because he said it was nonsense for a well man to take medicine. He never saw but one steamboat in his life and that was on the Missouri River. It must be remembered that the patient has lived in Portland since last August. On questioning he knew nothing of Portland, nothing of his house which he and a chum had built, and nothing of the chum or anything related to him. Although he had never seen a steamboat except one on the Missouri River, in another self he had fired on the steamer *Columbia* between San Francisco and Portland and had become very seasick. Furthermore, numbers of river steamers and ocean liners are to be seen daily in the Portland harbor on the very beach of which he has lived since August. Absolutely no clue could be hit upon by which to connect him with the life he lived in Portland. Letters on his person were strange to him and their contents worried him.

The next day, April 3, with his consent, he was hypnotized, so as to be thrown into his former self again in order to ascertain the events of his life since September, 1899. Hypnosis was again slowly induced. When completely under the hypnotic influence no answers could be elicited from him at all. By shaking him after suggesting his Portland life to him he roused, but in a delirious state, raving with headache, complained of two red men who twisted his head and begged to be taken back to the hospital, supposing he was down town. This was evidently the stage in which he was at times after the accident on the barge. No persuasion could quiet him, and to satisfy him we told him we would take him back to the hospital. On opening the door into the corridor leading to the ward, his surprise and alarm at finding himself in a strange building threw him into a frenzy of terror, and all we could do was to take him back to the dressing-room where we had been. Here he quieted down and went to sleep on the dressing-table. After about ten minutes I cleared my throat. He started up in a fright and began chasing rats on the bed. Again I quieted him. After sleeping a few minutes, without perceptible stimulus he started up again, but on seeing me, said in a perfectly calm way, "Where is Dr. Cobb? Did I tell you what I did since the accident on the barge?" (Dr. Cobb had been unavoidably called away after he fell asleep on the table. With the exception of these ten or fifteen minutes there were always from one to six witnesses beside myself.) He was back again in the self in which he was before the accident on the barge and knew absolutely nothing of the twenty-four hours which he had just passed in a different personality. No clue could be hit upon by which to connect him with it. He thought it was April 2, and on being told it was April 3, was somewhat surprised and supposed we had kept him hypnotized for twenty-four hours. The following history was then taken, the man apparently normal except that the old headache was back again. His life was traced backward and found to lead from Portland to San Francisco, Denver, Cheyenne, Wyo.; Edgemont, S. D.; Chadron, Neb., and finally to Glenrock, Wyo. Here he said his father and he had some sort of trouble. Could not tell how the trouble arose. His father threatened to shoot him and he ran away.

Omitting again the many details which are confirmatory and interesting, but not absolutely necessary to the narration of the case, he went to Chadron, Edgemont, Cheyenne, Denver, San Francisco, and finally to Portland. It subsequently developed that he also spent a period of time belonging to this life when about sixteen years old, *i.e.* previous to the Glenrock quarrel with his father. In this personality he knew nothing of coal mines, though he had been working in a coal mine in his other personality for two weeks previous to the quarrel with his father. Again repeated attempts were made to connect the two lives by going over, in detail, the experiences as related by him in the two respectively, but no connection could be made between them. By putting together the two histories there still remained large gaps which were unfilled by the experiences related while in the two respective personalities. The gap from Chickamauga to Oxford and numerous others of less importance remaining unfilled and having received confirmatory evidence from answers to letters of inquiry sent out, I felt sure of a third personality and hypnotized him, April 24, to throw him into said suspected personality. He was successfully thrown into it, and when he roused from hypnosis into the third state he was again a stranger to us and his surroundings. Acting on the difficulty experienced in gaining his confidence when he awakened the first time in a strange personality, I had written letters at that time explaining his condition and also a note which he signed to act as corroborative evidence of our friendliness, should he in the future wake and be a stranger to us. These letters were carried continually in his pocket, and were valuable aids in keeping the man's confidence in the different personalities. Some time was thus spent in reassuring him after which the following history was taken, unessential details being omitted in this report. When questioned in regard to Chickamauga and his experience there, he said he did not belong to the army there, but there were a great many soldiers all over the fields. He said, "I was awfully sick and I haven't got over it yet." In this personality he suffered continuously with pain in his head and abdomen. He was a typical tramp throughout, beating his way on trains, and working only enough to support life when it could not be done otherwise. He described in minute detail his wanderings through Chattanooga, Nashville, Green Brier, and Springfield, Tenn.; Henderson, Ky.; Evansville, Ind.; Carmi, Ill.; St. Louis, Jefferson City, Kansas City, Liberty, Red Cloud, and Oxford, having isolated and disconnected experiences in Cheyenne, San Francisco, and Portland. Here again repeated attempts failed to connect him with either of the other two lives. Frequently, in relating his experiences in the three different lives, he would come to a certain point in the narration, stop and say, "I can't remember what took place then; the next I remember I 'woke up' at such and such a place." In narrating the experiences of a different life he would pick up the interval which he forgot in the other life and carry you to the point where he said he "woke up" and then say "I can't remember what took place then, the next I remember I woke up at such and such a place." Thus the story of each life contained numerous unfilled gaps which would be accurately filled in by experiences in another life. By taking the three lives and writing the stories as they dropped and picked each other up, thus filling up the gaps of each, I was able to fill out almost completely his entire life from 1879 to 1902. There still remained a number of gaps, indicated by the stars in the schedule below, which I have been unable to fill out. Thinking that perhaps these gaps might be filled in by getting a still more complete history of the three lives, on April 26, he was thrown by hypnotism into each of the three lives successively and questioned closely in regard to the lapses without avail. The histories given were not related by him while hypnotized. Hypnotism was used merely to accomplish the transfer from one personality to another, and the history was then taken during full consciousness in the ensuing personality.

Once of his own accord and twice by hypnosis he passed into a state which could not be connected with the other three and in which he was in a state of semi-delirium. The subject became impatient and resented the frequent hypnotizing, and so it was decided to attempt by suggestion during the hypnotic state, accompanied by repeated consecutive narration of the events of his different lives to unite them into a unitary consciousness. The attempt was made April 28, and proved gratifyingly successful. For a day or two he was still unable to recall a short period immediately following his lapse at Chickamauga, but later that came to him with full vividness. On April 30, after having been hypnotized and the suggestion made that he would remember even the events comprising the gaps as yet unfilled, he was able to fill in the gap preceding the waking on the bluffs above Kansas City and the one preceding his waking in Liberty. The other gaps starred still remain a blank to him. With these exceptions he now tells a story of his life so continuous that he himself cannot tell where the breaks in the continuity used to be. On being told that a short time ago he did not know many of the things he was now reciting he answered, "Yes I did I always knew those things." It is only when he recalls the events of the past month that he realizes there has been any change in him.

Immediately before uniting the three personalities the following chronological tabulation of his experiences and changes of personality was made out and used as a basis for suggestion by which to unite the three selves. The stars indicate the gaps existing just previous to the time the three personalities were united into a unitary consciousness. These gaps have been partially and tentatively filled and classified in a manner to be explained below. The dates mentioned have been verified by correspondence. The different personalities will be designated by X1, X2, and X3.

X1. Nemeha City, born December 15, 1879; Nebraska City, six years old; St. Paul, Neb., nine years old; Crawford, Neb., fifteen years old. Changed in the depot to

X2. At Crawford, April, 1896; Edgemont, S. D.; New Castltle, Wyo. On way to Cambria, changed to

X1. Cambria, Wyo.; Crawford, Neb.; Havensville, Kan., August, 1896; Topeka, N. Topeka, Holton, Havensville, Kan.; Nemeha City, Neb.; White Cloud, Bloomington, August 12, 1897. Omaha, Ashland, Lincoln, Neb., May, 1898; Chickamauga. Changed while asleep under a tree to

X3. At Chickamauga, June 3, 1898. Chattanooga, Nashville, Green Brier, Springfield, Tenn. Henderson, Ky.; Evansville, Ind.; Carmi, Ill.; St. Louis, Jefferson City, California, Missouri. On train going toward Kansas City changed to

**a. (Probably X1; see below.)

X3. "Woke up" on the bluffs above Kansas City in the weeds. Crossed Kansas River. On freight changed to

**b. (Probably X1; see below.)

X3. "Woke up" in Liberty, Neb. To his surprise he had money in his pocket. Bought ticket to Red Cloud. On train changed to

**c. (Probably X2; see below.)

X3. "Woke up" in a shock of oats near Oxford, Neb., fall of 1898.

X { X1, X2, X3 } Oxford, Mascot, April 18, 1899. Holdredge, Neb. (Vague experiences recalled at these places in all three personalities. Most accurate and detailed account was given by X3. X2 only knew that he had been there.)

X1. Holdredge, Neb.; Glenrock, Wyo. Changed to

X2. At Glenrock, September, 1899; Chadron, Neb.; Edgemont, S. D., February 5 to April 12, 1900. Alliance, Sidney, Cheyenne, Wyo., June, 1900. Changed to

X3. In Cheyenne. Bought ticket to Denver. In Denver changed to

**d (See below.)

X2. "Woke up" on Larmour street, Denver. San Francisco. In barracks asleep and changed to

X3. Left the barracks and went out into a big city. Changed to

X2 In the wholesale part of San Francisco, Cal. Oakland. On train and changed to

**e (Probably X3; see below.)

X2. "Woke up" in Salvation Army Hall in Oakland, San Francisco. Portland, August, 1902. Changed to

X3. After the barge accident, February 20, 1902. In hospital three weeks. Changed to

X2. Hypnotized April 1, and changed to

X1. For twenty-four hours. Hypnotized April 3, and changed to

X3. Slept and changed to

X2. Till April 14. On way from hospital to my office changed to

X3. Took ferry to Albina. Changed to

X2. At Albina. Hypnotized April 24 and changed to

X3. Slept and woke from X3 to

X2. Hypnotized April 26 and changed to

X1. History taken. Hypnotized and changed into

X3. History taken, hypnotized and changed to

X2. Hypnotized April 28 and X1, X2, and X3 united.

There were other very brief lapses, judging from many incidents narrated. Several such lapses occurred probably at San Francisco and here in Portland. The lapses **a, **b, and **d he was able to fill in after the uniting of his three lives. In **a he went to Kansas City, climbed the bluffs and went to sleep in the weeds. This was likely X1, inasmuch as he started in the direction of his old home, and in X2 he knew nothing of his people at this time. In **b, as filled in by his united self, he went to Topeka, Holton, and Havensville. Here his people would have nothing to do with him, and he went to Summerville and then worked near Liberty for some time. This must have been done when X1, for it is only as X1 that he knew anything of his people at Havensville. The lapse **c must have been in X2, because when in this personality previous to uniting the three he said he had been in Red Cloud, but could not remember anything about it. In lapse **d he went to Denver and loafed around for about a week. The lapses **e and **f are still in obscurity, but assuming that there are only three personalities in the case these lapses must have been spent in X3, because he changed to them from X2 and X1, knew absolutely nothing of any time between September, 1899, and April, 1902. Evidence seems to point to the conclusion that whatever personality or personalities he was in while at Oxford, Mascot, and Holdrege, there was at times more or less knowledge of all three selves at those places. In no single personality could any specific detailed acount of his stay at Oxford and Mascot be given, though in all personalities he knew that he had been there. X3 gave the most details of any at these places. Either there was a certain amount of interfusion of the three personalities at these places, or else he had frequent changes in Oxford and Mascot. Subsequent correspondence with his acquaintances at Oxford substantiates the former view. Furthermore, he says that while he was asleep in the shock of oats near Oxford he had a very peculiar dream of having been in Red Cloud, etc. It is highly probably that this dream was not a dream, but the real experiences of the preceding lapse, probably filled by X2 or a modified X3. This vague interfusion of the selves or modification of a particular self may account for all the lapses and peculiarities in X3 from Chickamauga. Though there is no absolute proof, the data at hand leave one in the conviction that at Oxford, Mascot, Holdredge, and probably Glenrock there was a partial, if not complete, fusion of the experiences of the three lives, which was confusing to him then as well as to us now. His acquaintances at Oxford looked upon him as insane.

Though his experience from Chickamauga to boarding a train near Kansas City was given in the most certain and positive way while in X3, and though he had no relatives that he knew of in this personality, yet it is probable that during that time he had inklings of his former life from some source or other which led him back to Nebraska. He may, however, have learned that he belonged in Nebraska by letters in his pocket or other means in camp before leaving Chickamauga. It seems probable, taking everything into consideration, that there was slight knowledge of his other lives in this personality.

That the uniting of his three selves into a conscious unity did not insure against subsequent lapses is shown by experience later. On May 7 he came to my office feeling badly, suffering from headache, and depressed in general. I hypnotized him and suggested that on waking he would feel better. He woke and seemed better. After sitting for several minutes he looked about, somewhat surprised, and without any visible signs of change, he remarked, "Doctor, I have been asleep again." The last he could recall he was entering the building and waiting for the elevator, but how he reached my office and all that transpired in the meantime was an utter blank to him. His partner, with whom he lives, says that such lapses used to be rather frequent with him.

In order to verify the history of the case numerous letters had been written to parties mentioned by X1, X2, and X3; one of these letters was sent to the army post at San Francisco to inquire as to his enlistment and desertion from the army as a result of a change of personality, but no answer was received. On May 14, acting upon information gained from my letter to San Francisco, officers from Vancouver Post came and arrested X, and took him on the car to Vancouver, charged with desertion from the army at San Francisco. On May 16, at Vancouver, I presented the history of his case to the officials in order to obtain his release. After the conference with the officials X was brought in. To my surprise he was X2 again; knew absolutely nothing of X1 or X3 or of his experiences subsequent to uniting his three selves. Only X2 was known to him. After hypnotizing him and suggesting that he would remember all his life again he woke with full memory of X1, X2, and X3 as before he was arrested.

So far twenty-eight letters have been received in answer to inquiries sent to relatives, acquaintances, war department, etc., each and all of which verify most accurately the history described. Changes of personality took place twice while in the army and he was recorded and hunted as a deserter. He enlisted the first time as X1, the second time as X2, and each personality knew nothing of the other enlistment. At first these two desertions raised a suspicion in us that he might be deceiving in order to cover up his guilt, but second thought, on the contrary, confirms his duality in the two acts, for a deserter would scarcely run the risk of reenlisting. Furthermore, proof that he had changes of personality previous to any connection with the army in addition to confirmatory evidence from numerous other sources removes any possibility of insincerity on his part. Aside from the corroborative evidence, observation of the man during treatment would have been sufficiently convincing to remove all doubt.

X1 was perfectly well, jovial, bright; knew the names and addresses of all his relatives and could give an accurate account of his boyhood days. He had rather accurate dates for everything. Was eager to educate himself, though he was only an ordinary laborer as a rule. X2 was quiet in disposition, preferred to be alone, had spells of sleepiness, always had some headache, knew but little of his relatives, and that was learned subsequent to age eighteeen; a good mechanic, ambitious, and inventive; desirous for an education and distinctly religious in character. All in all, his life bore a sad melancholic aspect. X3 was a typical tramp, largely due to the fact. no doubt, that he began this life where he did. Though eighteen years old at Chickamauga, when asked where he came from he answered "didn't come from any place." Worked only enough to exist; severe pains in head and abdomen; always hungry; all in all, a lower type of man by far.

All three personalities had a remarkable memory for details. The same name was retained in all. In addition to the three personalities described there was still another state which may possibly be a fourth, but each time he was thrown into it he was semi-delirious and no definite information could be obtained from him. The place of this state, in its relation to the personalities described, is difficult to determine. In it he raved with pain and was always thirsty. This state *may* account in part for some of the gaps remaining unfilled.

In his united self he is radically different from what he was previous to the barge accident. Previously taciturn and fond of solitude, in his united self he became social and settled moodiness disappeared. He still manifests the old ambition for an education, though at present he chafes under the monotony of his wait in prison until the routine of government formalities shall be accomplished. Under the circumstances his ultimate release would seem to be a mere matter of time, but the worry and mental excitement incidental to his arrest give him almost continuous headache, and at times plunge him into a despondency which makes him wish he were dead.

After the fusion of his three lives the first time, a minute and detailed history of his boyhood and early manhood was taken in order to see if any cause of the trouble could be detected. As a boy he received very rough treatment from his father, but no definite etiology of his condition could be discovered. Though changes of personality occurred two or three times under what seemed to be a definite etiological factor, such as the fight at Glenrock and the fever at Chickamauga, yet these things cannot be considered the sole cause of the trouble. In the great majority of cases his changes of personality took place while on a train or immediately following—a fact not without significance.

The changes from one personality to another were at times gradual, instead of abrupt. At times memory of one stream of consciousness faded out gradually as the other came into prominence. One of the changes which occurred in my presence was of this type. Several times in one personality short preceding experiences were vaguely recalled and thought to have been dreams, showing that at times either the different selves overlapped, as it were, to some extent, leaving the period of change indistinct in each, or else—what is more probable—the events supposed to have been dreamed were experiences of the same self under a sort of psycho-epileptic seizure. Under the latter supposition the gap **c in the schedule above may be a sort of psycho-epileptic mutation of X_3 instead of a change into X_2. The whole process throughout might not improperly be called a psycho-epileptic exchange of personality.

The personality, designated throughout this article as the "united self," cannot be considered as *composed of* X_1, X_2, and X_3, as constituent parts, but, strictly speaking, the so-called "united self" is a new unified experience even as X_1, X_2, and X_3 were originally. This was clearly exemplified by the fact that after his return to X_2 at Vancouver subsequent to the uniting of X_1, X_2, and X_3 in memory, he not only knew nothing of X_1 and X_3, but the experiences of the so-called "united self" were also a blank to him.

Dog Eat Dog.—An Indiana physician has sued a fellow practitioner for $1,000 for professional services rendered in the course of two years. The plaintiff claims that he cured the defendant of a disabling affection of the foot, as a result of which he was enabled to resume practice, and thinks he should profit by the increased earning capacity which his patient now enjoys, presumably as a direct consequence of his treatment.

SOME HINTS TO THE GENERAL PRACTITIONER ON THE TREATMENT OF CHRONIC NASOPHARYNGEAL CATARRH.*

By W. FREUDENTHAL, M.D.,
NEW YORK.

CONSULTING LARYNGOLOGIST TO MONTEFIORE HOME, BETH ISRAEL HOSPITAL AND BEDFORD SANATORIUM FOR CONSUMPTIVES, LARYNGOLOGIST ST. MARK'S HOSPITAL, ETC.

In attempting to present some of the modern views on nasopharyngeal catarrh, the writer has not done so on account of the many new points which he is able to bring forward, but in the hope of eliciting a thorough and fruitful discussion of the subject. Chronic catarrh of the nose and throat is so common, especially throughout the United States, that every practitioner ought to be familiar, in a general way, with its treatment. But let me ask you right here: "Do general practitioners always recognize it? Do they always examine for it? Are they not too apt, in too many cases, to accept the statement of the patient, make no examination, prescribe a nasal douche and some wash, and allow the patient to disappear, perhaps to excite, in time, a catarrh where none existed before?" (Lefferts). We shall see later what we are able to accomplish and what not. Before, however, entering into the details of our theme, which was selected by your president for discussion, I beg your indulgence for a few remarks on the etiology of catarrh. You will then, perhaps, better understand some of the therapeutic measures which I regard of great importance. Let us consider the etiological factors producing the chronic catarrh of the nose, of the pharynx, and of the retropharynx. To my mind they form a unit and must be dealt with together.

In almost all the textbooks, and in the many articles on this topic, which would fill a library, you will find the naïve statement that a chronic catarrh is the consequence of an often-repeated acute catarrh. We all know that! We further read that we ought to avoid acute catarrh in order to prevent it from becoming chronic. The most contradictory rules are given for that purpose. In a somewhat elaborate article in v. Leyden's *Zeitschrift für diät. and Phys. Ther.*† I have discussed the various methods of prevention of acute catarrhs, and it is not my intention to repeat them here. What I would say is that in your practice you will meet much oftener with acute exacerbations of chronic catarrhs than with fresh colds, no matter whether these acute exacerbations consist in a coryza, angina or acute bronchitis.

It is my object to discuss especially the chronic forms. For a long time the belief prevailed that Americans were especially disposed to catarrh, the contributing causes being sought in the marked humidity of the atmosphere, especially along the coast, the sudden changes in the temperature, the dusty and unclean streets, etc. Even Morell Mackenzie, after traveling in this country, attributed the prevalence of post-nasal catarrh in the United States, chiefly to the changeable character of our climate, to the large amount of dust, and to the habit of fast eating and drinking and his ideas have been disseminated by the textbooks abroad and in this country. There is dust in other parts of the globe; there are plenty of dirty streets elsewhere—although our metropolis has occupied quite a prominent place in this respect of late—there are fast livers all over the world, and still nowhere else is to be found such a multitude of people suffering from catarrh. What is the reason for this? What is the real cause of this peculiarity? I found no satisfactory explanation whatever until I began to investigate things myself. I studied the mode of living prevalent here and other factors in American life. Perhaps, I was better adapted for such an investigation than those of you who were born in this country, as everything was strange to me, much being just opposite to what I had been accustomed to see, and thus naturally being brought vividly to my notice. What then are the conditions especially prevailing here which have a special bearing on our question? If we compare our mode of living with that of a hundred or two hundred years ago, we must confess that we have returned to a very ancient style of living, we have become *mutatis mutandis* actually cave-dwellers again. In a ten by fifteen room the average human being passes twenty-three of the twenty-four hours of the day, or even more. The room is nothing but a cave-dwelling, with the exception that it is tightly closed from all sides during the greater part of the year. It makes little difference whether we call this cave a sitting-room in a fashionable house, or whether we term it a sweat-shop. The difference is only in degree. The room is, as a rule, tightly closed against the invasion of fresh air. If we speak of climatic influence, and there certainly is such an influence, it is the climate of our rooms—of the caves which we inhabit, which we must study. It is immaterial what is the temperature, the degree of moisture, or the winds at Sandy Hook. The three million of inhabitants of our city do not live there, and it does not matter to them whether in the harbor of New York there is a great deal of moisture or not. When physicians say there is so much catarrh in our region on account of the great humidity of our climate, we must regard such statements as pure nonsense. Too much moisture will never set up a catarrh, and especially not that form of catarrh which you see mostly, and which is called the dry catarrh.

---

*Read at a meeting of the Eastern Medical Society, December 27, 1901.

† Ueber das Wesen der sogen. Erkältungskrankheiten. 1899. Bd. iii, Heft VI.

As I consider this point of the greatest importance, I hope you will pardon me if I dwell upon it a little longer. Over ten years ago I commenced my investigations regarding the amount of moisture in our houses, and have been surprised at the results obtained. It had been shown by various experiments that the atmosphere of a room in winter should be kept moderately humid, *i. e.* it should contain between 50 and 60 per cent. relative humidity. The minimum point should never drop below 40 per cent., while a relative humidity of 70 per cent., or even 75 or 80 per cent., is still agreeable and is not considered unhealthy. Now I have made frequent tests of late again, and I have never seen a relative humidity of 50 per cent. in New York houses. When the outside temperature was around 30° F., I have never observed even 40 per cent. The highest point reached was 30 per cent., but 25, 20, and even 18 per cent. relative humidity, was nothing unusual during a protracted period of very cold weather, when the rooms were not at all, or but very little, aired. Now how does it happen that we are affected with dryness while an atmosphere laden with humidity surrounds us on all sides? I explained that in an article, to which I would refer those interested in this question.[2] To-night allow me to mention only the most common factor in this connection, *viz.*, the heating of our houses. The Mexican peasant, I am told, puts on a heavier coat when he enters his cold hut. He does not heat it, because he believes that wherever there is a furnace there is tuberculosis. Perhaps there is some truth in that. The fact is that every form of artificial heating is detrimental to health, most of all, however, the hot-air furnace. You are all familiar with this method of heating. The shaft which conveys the so-called fresh air to the furnace is situated near the ground and is in close proximity to the kitchen. This shaft is so poorly constructed ninety-nine times out of one hundred that the bad air in the cellar has free access to it. The air from these sources is heated in the furnace and passes into the rooms. This impure air is warmed, that means that it is deprived of the greatest part of its humidity, if not all of it. In this condition of dryness it reaches the rooms wherein we live. There it has the effect of drying the air already present, and it is evident the colder the atmosphere is outside and the more we heat our furnace, the dryer will the air become in our rooms.

This dry air we have to inhale, and it is from this point of view that I consider the etiology of chronic rhinitis, chronic post-nasal and chronic pharyngeal catarrh common. I have shown this to be true of post nasal catarrh, and it is only one step further to demonstrate its correctness for catarrh of the nose itself and for that of the pharynx.

Before a special society, not far from us, there was last year a discussion on atrophic rhinitis. All sorts of theories were advanced, but the most plausible one was not touched upon at all. The main symptom of a dry catarrh is its dryness, and is it not natural that the dryness of a physiologically moist mucous membrane must depend upon the atmosphere surrounding us? Still nobody has thought of that. One of the functions of the nose is, according to the investigations of Aschenbrandt, R. Kayser, E. Bloch, and the writer, to charge with moisture the inspired air. This, according to my own experiments, is even more the case in the retropharynx. Now when we inhale such abnormally dry air, as shown above, the nose will perform its functions for a long time until the mucous glands have no more moisture to give off. First, through increased activity of all parts of the mucous membrane a hyperæmia will set in, then a hypertrophy, and after a long period an atrophy. This holds good with some modifications for the pharynx, too, when the process extends downward. This atrophy affects not only the mucous membranes, but also the underlying bones, and we get the picture of atrophic rhinitis so familiar to you all. The atrophy sometimes shows itself very remarkably. In one case which I observed not long ago it had attained dimensions such as I had never seen before. All the middle and inferior turbinated bones had shrunk to mere rudiments. Of the left lower turbinal there was hardly anything at all visible. After careful examinations absolutely no signs were to be found of specific infection, neither hereditary nor acquired.

Hopmann and Zaufal regarded the ordinary atrophy of the turbinals as congenital. But this is surely not so, as Zuckerkandl found none in 252 skulls of infants, which he examined. The cause is to be sought in the desiccating influence of the inspired air, an influence brought to bear upon the tissues of the nose for years and years, and finally ending in atrophy.

In 1896 an interesting paper was published by Goodale[3] of Boston, which I would like to mention here. It has some bearing on our subject, but the author does not reach the conclusions I do.

When we speak now of the therapeutic measures at our disposal for combating this disease it is difficult to draw the line between the specialist and the general practitioner. But believing that the latter ought to do just as much as he is capable of doing you will permit me to place before you what I consider of most service, leaving it to individual discretion how far to go. Nevertheless, almost everything that will be outlined by me can be accomplished by every one who is familiar with the method of inspecting the interior of the nose and can manipulate a few instruments. He will relieve his patients considerably, as the symptoms and different disturbances resulting from this disease are very numerous.

In the treatment of chronic naso-pharyngeal catarrh the hygienic part is far more important than the medicinal. A change of climate is often of great benefit to these sufferers. Now, where shall we send them in summer? If you consider what I have said on the subject of etiology, you will naturally come to the conclusion that the seashore is the best place for them. Well, it is—and it is not. Unless the patient be very old, sea bathing is beneficial in most instances. Very old people, especially those with heart lesions, often do not react well after a seabath. But there are people who go to the seashore, but do not bathe except in a tub. These persons may better stay at home where they have more convenience, and, perhaps, more recreation, or, better still, seek the mountains. By bathing, and especially by diving under the waves, the entire upper respiratory tract is cleansed and stimulated in a most remarkable manner. The patient feels like a different being, most of them almost believing that they never had any catarrh. Even Woakes, whose views are often different from mine, acknowledges in his excellent book on post-nasal catarrh that "with the return of summer and a seaside visit, all these symptoms diminish." Swimming is especially to be recommended, and I believe that every child ought to learn how to swim. And let me tell you right here, that there is no such thing as a "cure" of twenty or twenty-one seabaths. The number is entirely arbitrary. Any one suffering from chronic catarrh may take as many baths during a season as he enjoys if he is otherwise healthy. If he should be rheumatic or otherwise affected, we would have to be guided by other rules. The same law holds good for the duration of a single bath. A healthy person can do a great deal that a weak and debilitated one should not risk. For many years, whenever at the seashore, I have been in the habit of taking two baths every day, and stayed in the water just as long as I enjoyed it, which in the middle of summer was sometimes between one and two hours, and I could not observe any ill effect from this. The seashore, therefore, is of greatest benefit to many. I will say here that I prefer the coast of Long Island to that of New Jersey, as it is so much cooler in summer. But there is a class of patients who never feel well and comfortable at our seashores. If it is hot they feel so much oppressed by the terrible heat, the lack of wind, etc., that they can hardly breathe. I said *our* seashores, as elsewhere conditions differ materially. Thus, for example, I have sent a good many of such patients to the Baltic Sea or North Sea, especially Norderney and the vicinity, where they felt splendid and enjoyed themselves immensely. But we cannot send everybody abroad; we do best, therefore, to advise this class of patients to go to the mountains. We have so many naturally beautiful places in our State and some of the neighboring States, that we can provide for every patient a perfect change of climate. Whoever is at all fond of nature will find some attractive place. A mountainous region with a lake in which the patient can bathe is the ideal condition. But the trouble is that, especially in the Catskills, our nearest mountains, there is by no means an abundance of lakes or running water; and, furthermore, comparatively few people can make a prolonged stay in such resorts, while a great many can take a sea bath during the entire summer.

So far for the patient's residence during the summer. In winter it is desirable to send these patients to places with a moist, mild atmosphere, it matters not whether at the seashore or even inland. I am glad Professor Chiari[4] of Vienna is quite in accord with my own ideas on this subject, and advises a moist atmosphere.

But what can we do for the vast majority who stay at home during the winter? There is a great deal to be done and much can be accomplished by it. As we cannot afford, like the Mexicans, to live in unheated houses,* we must try to relieve the dryness of our rooms in every way possible. Firstly, the windows in every room should be opened frequently. It is not sufficient to say that the windows in a bedroom have been open from one to two hours in the morning. It is important that they be opened immediately before retiring. If you can provide some form of ventilation for the bedroom, do so. But it is amusing to see people open the window at the top a few inches and then pull the shades and curtains down so that the quantity of air that enters such a room can be measured by homeopathic scales. I advise my patients, whenever they feel a dryness of the nose, the throat, or the lips, to have a steam atomizer in action for from five to twenty minutes, thus moistening the air of the room for a certain time. A little salt may be added. As this procedure is quite harmless, you can repeat it frequently. I especially order it before retiring and immediately after rising. There are some persons, however, who will not do this, as it appears to them too simple a prescription. In such cases they are told to inhale the steam through the nose, adding to the water a few drops of oleum pini sylvestris, oleum terebinthinæ, eucalyptol, and similar drugs. The desired effect, you understand, does not lie in the drug, but in the moisture that is thus brought in direct contact with the mucous membrane. There have been put on the market different apparatuses for moistening the air as soon as it leaves the register, but all of them, as far as I know, are entirely unsatisfactory.

Bathing in Winter.—How shall we bathe in winter—cold or warm? There is no doubt that cold bathing in winter is very invigorating and a great preventive against catching cold. Besides this it does little to alleviate the unpleasant symptoms of our patients. The amount of moisture that is absorbed by the system during a cold plunge of two to three minutes or a cold douche of one to two minutes' duration is comparatively small. If we want more humidity (and more is necessary) the bath must be taken lukewarm. My patients undress completely in the bathroom while the hot water is running down from the douche. Before the tub is half filled with hot water the whole atmosphere of the room is saturated with steam. By adding cold water the temperature of the bath-room becomes tepid. After remaining in it about ten minutes the patient should stay in the bath-room another ten, fifteen, or twenty minutes dressed, or still better, undressed. I allow no gas stove in the room. If the patient feels chilly sitting naked, all he needs to do is to turn on the hot water again and very shortly the room is filled with heat and moisture. If the patient before going into or after coming out of the bath exercises with dumb bells or Indian clubs or anything similar, this will be of advantage. The lower respiratory tract thus becomes charged with moisture, while there will be a reserve supply for the time when the upper parts become dry again. These are things which most people can do in their own homes, and without any extra expense.

---

*I know of a few physicians in this city who do not keep their furnaces going; they try to get along with gas-stoves and open fire-places.

There is, however, a great need for something more than this—that is, swimming baths. We have some, but they are entirely inadequate for such a large population, or they are too dirty to be used by many. Is there no colleague who has commercial enterprise enough to build such a natatorium? While traveling abroad I found the finest establishments of this kind in Frankfort on the Main and in Munich. They seemed to me absolutely clean and at the same time practicable for the use of a great many people. These natatoria are not intended for the poor alone, but also for the well-to-do who used them equally there; also in Germany there are some schools equipped with swimming tanks, which have proved to be of great utility. I hope this idea will be adopted here.

In the general hygienic management of our cases fresh air is of vital importance, and patients should be as much out of doors as possible. Walking, riding on horseback, wheeling, rowing, golf, baseball, tennis, and similar games cannot be recommended too highly. If you want to keep your children healthy do as I do with mine. Take them out when it snows and when it rains. Leave the rubber shoes and umbrellas with the other relics of times gone by. When your children play and run about in the snow and get warm they will be healthy. If you keep them home and make hot-house plants of them they will be sickly and you will be responsible for it. Why? The superstition about the necessity of wearing rubber shoes is so strong that one day I was sent for by the principal of a school. One of my children had gone to that school on a rainy day without rubbers and the lady thought that that was against the rules. *Sapienti sat!*

We now come to the treatment of nasopharyngeal catarrh by local applications. If polypi are present in the nose or large hypertrophies or affections of the accessory sinuses or lymphoid hypertrophies in the vault of the pharynx or other pathological conditions requiring surgical intervention, they should be treated in that manner.

If the hypertrophy of the turbinals is not very large, it should not be cauterized nor snared off. If you treat the always concomitant post-nasal catarrh, the hypertrophy will shrink of itself after a few post-nasal applications, and you will note that the hypertrophy was almost beginning to undergo an atrophy. I have become very skeptical regarding the value of cauterizing hypertrophied turbinals, as I have seen too many atrophic catarrhs follow the procedure. With any post-nasal applicator I remove the dried crusts and scabs from the retropharynx, at the same time applying a mild or strong Lugol's solution to the mucous membrane of the retropharynx, and if necessary also to that of the pharynx. Many prefer a spray or even á syringe used postnasally, and these often do good. But I have seen acute middle-ear catarrh result from syringing the retropharynx. Some patients do not learn to use the syringe, and the danger is great when we persist in its use.

If the hypertrophic stage has passed and atrophy set in, then our tasks is much harder. The first thing is to remove the scabs, etc., from the nose. In the claims made for different proprietary douches, sprays, etc., special stress is often placed upon the words cleanliness and godliness; but we know that people with atrophic catarrh are just as clean as their neighbors. With cleanliness alone we will never cure an atrophic catarrh. As the scabs, however, must be removed, I insert for this purpose tampons saturated with ichthyol (5 per cent., 10 per cent., 25 per cent.), and leave them in for about ten to twenty minutes. On removing them, and after having cleansed out the retropharynx, the patient can blow his nose and clear it of every obstruction that had been present. If the patients can insert the tampons themselves, I give them a weaker solution, and let them do it at their homes. In advanced atrophic catarrhs one tampon is inserted, say in the right nostril for two hours in the morning, and in the left one for two hours in the afternoon. Instead of ichthyol other drugs may be used, as, for example, a preparation called keroline-ichthyol (5 per cent. to 10 per cent.), that was recommended quite some time ago, or resorcin, etc. Generally, a nasal douche or nasal spray, or even the syringe, is recommended. But they are not free from risk. Do not forget that every stream of water that runs through the nose is injurious to it, and there is still more danger from this when the mucous membrane is in a pathological condition. I am of the opinion that these douches and sprays have done more in producing affections of the accessory sinuses than anything else. It is true that a purulent process is not always developed when a fluid containing staphylococci and streptococci is forced into one of the accessory sinuses. The natural protective agencies often prevent such an occurrence. It was Bresgen,[6] who already, in 1891, showed that especially the sinus frontalis and maxillaris can become affected in this way.

Still there are cases in which it is necessary to use some kind of a douche or spray. I employ them when other means do not help, and only with all the precautions possible, regarding them as an adjunct in the treatment of these catarrhs, and nothing more. But we must always remember that if we add any drugs to the fluid, only the least irritating ones should be applied. I must warn here against the indiscriminate use of so-called cleansing snuffs and washes. One physician has advised that every child's nose should be washed daily with a saline or alkaline solution. He claims that in dentistry the same principle of cleanliness has been insisted upon for a long time; why should not the rhinologist follow in the dentist's footsteps? If we argue in that manner, let me ask why, reasoning on the same lines, do we not pump out the stomach twice a day? We should surely find much undigested food residue. Why not wash out the healthy urethra and bladder daily? Why not irrigate the whole intestines by antiseptic solutions, etc., *ad infinitum?* Shall we not rather give nature a chance to do something for us? There are few things so useless, to say the least, as douching and spraying a healthy nose. In cases, however, in which there are masses of secretions, dried or not dried, which we cannot remove otherwise, we must use a douche like that of B. Fraenkel's or Dessar's or Bermingham's, or we might use any cup, or even an ordinary spoon. In cleansing the nose we often find dried secretions with a fetid odor originating from the retropharynx. In this locality—this quiet corner behind the portal of the breathing road with its nooks and recesses—the secretions easily collect and decompose. Often when we see a patient for the first time this odor is so marked that we are inclined to believe that it comes from one of the accessory sinuses. Many a time have I seen such dried masses in all parts of the nose, even in the middle meatus and near the frontal sinus. I have also seen operations performed in such cases on the accessory sinuses which were most creditable to the operative skill of the rhinologist, but of no relief to the patient.

Not everything that smells is an accessory sinus disease. You see the fetor disappear entirely in such cases after the hygienic and local treatment has been carried out for a little while.

Often we find an abundance of secretion from the nose and from the pharynx. The first we see very frequently in children even where we do not detect any adenoids. In fact, I believe it was Jacobi who said that this rhinitis is often the primary cause of the adenoids. For local treatment in such cases penciling with a 1 per cent. to 2 per cent. solution of nitrate of silver or 5 per cent. to 10 per cent. protargol, which every mother can do at home, has been of benefit if continued for two or three weeks. This discharge from the nose very often produces in little children the alarming symptoms of false croup. In grown persons it runs down, affecting the larynx, or it passes through the œsophagus into the stomach, where it sometimes causes troublesome disturbances. I remember an instance of a prominent colleague in this city who was sent, by the advice of his medical friends, twice to Carlsbad without any relief whatsoever. After he was treated thoroughly for his catarrh, he no longer felt discomfort from his stomach, and is well to-day—more than twelve years since.

For the last three or four years I have used carbonic-acid gas for local treatment. Since trying it at the suggestion of Dr. A. Rose at my clinic, I found it to be a great assistance in certain forms of dry catarrh. I have noted over and over again that carbonic acid gas applied to mucous membranes brings on a hyperæmic condition. The patients say: Now I can breathe well. In some cases it has really an excellent stimulating effect. But we must remember that the mucous membrane of the nose, as well as that of the retropharynx, has to be cleansed before using carbonic-acid gas. This is of the greatest importance. As most patients cannot themselves remove the masses from the retropharynx, this is one of the reasons of its failures when used at home. I have never seen any toxic effect from carbonic-acid gas excepting in one case. It was that of an old gentleman, seventy-three years of age, with mitral insufficiency. After inhaling the gas for about two minutes, which I always prepare in the old-fashioned way with bicarbonate of sodium and tartaric acid, he fainted away, but soon came to without any special effort. This case reminds us to be always on the lookout even when we give medicine in harmless quantities.

Just as in all chronic diseases one drug loses its effect after it has been used for some time, so we have to change also the carbonic acid gas, and we have two more means at our disposal in order to stimulate the inactive mucous membrane, *viz.*, (*a*) internal massage and (*b*) the electric current.

Michael Braun of Triest was the first who tried to interest a larger circle, at the Berlin Congress, in the treatment by internal or direct massage. Soon afterward I began experimenting with it; but I was induced to work systematically in this field by the enthusiastic monograph of Laker.[7] And though at times, while reading his book, I felt that the author painted this new treatment in too brilliant colors, still I could not help thinking that, in spite of the severest criticisms, there was sufficient good remaining to warrant a trial of this therapy. Personally, I should like to state that I have no reason to regret my own experiments in this direction.

And these are the causes which led me, notwithstanding all objections made beforehand, to utilize electricity in preference to the muscular action of the arm as a motive power for massage.

In 1893 I published an article on "Internal Massage" (Medical Record, July 22, 1893), and at the same time introduced my electric vibrator, which I take pleasure in showing you again. It works with the greatest ease, and anybody who can hold a nasal instrument can manipulate it. I use it now almost entirely for atrophic conditions in the nose and throat. In which particular manner, however, an atrophic mucous membrane which, according to all our pathological and therapeutical experience, is no more able to perform its function can be brought back to its normal state, and especially what microscopical changes occur I do not know. I know only so much, that before treatment I had such very pronounced atrophic conditions in many cases that you would expect to find absolutely no glands in the mucous membrane left, and afterward, a mucous membrane not only normal in appearance, but also secreting mucous was the result of the treatment. The *Journal of Laryngology* (Editorial, June, 1892) says in this regard: "But the massage treatment of atrophic catarrhs would seem to hold out more favorable hopes than any other form of therapeutics, and this, indeed, is only what we should expect when we consider that such treatment must of necessity tend to restore the physiological integrity of a mucous membrane which has undergone trophic changes."

To my mind, after many years of trial, there is no doubt, that by internal massage, we produce renewed activity of formerly inactive glands, thus rendering them more prone to take up moisture and to retain it. If we accomplish this alone we have done a great deal for our patient. As a rule, I do not apply any medicament in connection with the massage, as others do. I want its pure effect. As soon after the massage as convenient I let the patients inhale from some steam apparatus. In this way we fulfill all indications.

Both the faradic and galvanic currents have been recommended, but they are very little in use nowadays for these affections.

There is one symptom often connected with chronic catarrh that is seldom mentioned in the textbooks, but is sometimes of great annoyance to the sufferer, and that is snoring. What is snoring? During normal respiration the soft palate by air pressure is drawn to the base of the tongue, and thus during sleep an open passage is created between the nose and the lungs. Persons with normal respiratory organs should therefore breathe during sleep "like a child." In so-called mouth breathers, however, the free edges of the velum hang loose, and with each act of breathing the incoming and outgoing air produces the familiar noise called snoring.

It is not seldom that I am consulted by people on account of snoring. This is not a bad habit that, as was formerly believed, is especially met with in chronic alcoholics, for as we now know every child with adenoids or every person with some obstruction in the upper-air passages snores. There is another group, however, where you cannot find any pathological basis for this snoring. I have to exclude here those patients who have been operated upon for adenoids. If there were present large masses of adenoids or other tumors, the soft palate, through permanent pressure, becomes extended, and sometimes it takes months before the restitution and integrum takes place. It is different in grown persons, where you often see no pathological changes at all, and still the patients complain of snoring. I am confronted with this "weakness" quite often in young people of either sex, who want to get married. They consult me, as a rule, a short time before their wedding, and are anxious to obtain some remedy. Now, what is the cause of their snoring? As I could not find a satisfactory answer to this question, I formed my own theory, and acted accordingly. I imagine that through one cause or another the soft palate has become relaxed, so much so that as soon as the patient lies down, and especially when he lies on his back, the palate falls back, thus closing up the passages between the nose and throat. It is easy to understand that in this way we get the same effect as if any object were to close up the passage, be it a tumor or dried mucous. In this latter class of cases I have applied alternately the galvanic or faradic current directly to the velum palati, and have had some very encouraging results. I would warn here against the often indiscriminate use of all kinds of devices to prevent mouth breathing during sleep. I consider them absolutely dangerous, and fail to understand how experienced laryngologists can recommend them. These "devices" consist in some bandage tied around the head and chin in order to close the mouth during sleep. In normal persons we surely do not need them, for every person with normal nose and throat invariably keeps the mouth shut during sleep. In other words, if any person sleeps with open mouth there is a pathological reason for it, and it is not merely a bad habit. Remove this cause and you need no "device." I believe that a swelling of the turbinated bodies occurs even in young children. This is sufficient to close up the nose, and prevent nose breathing. If you then close up the mouth, too, the child is in danger of suffocation. The reason that this accident has not yet been observed is that these children manage to open their lips to some extent and breathe through the spaces between the teeth.

I omitted to give you a mass of prescriptions for salves, vaporizers, gargles, etc., as you can find them plentifully described elsewhere. I use the different gargles and often to the benefit of the patients. I have tried here, however, to present some general rules.

It is our duty to relieve suffering humanity from their pains and ailments, and I hope that you will find in that little corner of our science called laryngology many occasions to undertake this Samaritan work.

The Treatment of Simple Obesity in Otherwise Healthy Persons.—Carl von Noorden says that of all methods, the slowly working ones are much to be preferred, especially in young people and in women in whom the abdominal fat must be decreased. The essential thing is so to regulate the manner of living by sensible rules fitted to the habits of the individual and carried out at home in the daily routine, that further deposit of fat is prevented, and that which is already present is diminished. The best method is the old-fashioned one of instituting short courses of treatment of four or five weeks' duration, at long intervals. At the same time it is well to make use of this opportunity to exercise and strengthen the muscles and to harden the skin. In many cases the adipose tissue is not deposited evenly over the body, but is very marked over the abdomen. In rapid courses the fat may be lessened elsewhere, but in the abdominal walls it stubbornly holds its own. In more slowly applied courses of treatment the fat disappears much more evenly; when this happens an equally distributed adjustment usually takes place later; that is, the abdominal fat is lessened and is scattered among the other fatty deposits, while the body weight remains the same.—*International Medical Magazine.*

The Successful Treatment of Tuberculosis and Lupus by Garlic.—W. C. Minchin is satisfied from his experience that no treatment has as yet been brought forward which will give anything like such satisfactory results as the use of garlic. He uses the freshly-expressed juice without removing the chlorophyll. In pulmonary cases he dilutes this pure juice with an equal part of distilled water and applies it upon the sponge of a large perforated zinc respirator. It is applied freshly two or three times daily to the sponge with a small brush. The respirator is worn as continuously as possible for the first few weeks, and after that for about three hours daily. When there is evidence of intestinal trouble he gives the fresh juice by mouth in doses of 20 m. diluted. In laryngeal cases he has met with success by using a 1 in 20 solution with an ordinary throat spray, using it frequently. In surgical cases and in lupus the undiluted fresh juice is used. Very unhealthy cavities should, of course, first be washed out with some antiseptic, when a little of the juice may be injected into the cavity, covering the outlet with a similar dressing on lint. In the case of lupus fresh juice should be painted over the affected parts every night and washed off in the morning with oatmeal water.—*Medical Press and Circular.*

Bacteriology of Acute Otitis Media.—H. Coussieu states that acute otitis media following an infectious malady of unknown bacteriology (such as scarlet fever or measles), is generally mono-microbiobic at its commencement. He finds as the initial germ the pneumococcus, streptococcus, or staphylococcus. He has never found the bacillus or Friedländer, but does not deny its existence under the conditions named. This monoform does not, as a rule, suppurate, or at most, suppurates for only a brief time. When we find at the commencement of an attack several associated germs, pathogenetic microbes, alone, or those associated with saprophytes, the otitis tends to become chronic. Organic tissue-changes predispose to secondary infections, which are frequently caused by catarrhal affections of the nose and pharynx. These act through the Eustachian tube. The surest way of avoiding these infections, and consequently to lesson the duration of an otitis, is to maintain as rigorously aseptic conditions as possible in the nose and pharynx. For this purpose resorcine, boric acid, and menthol are advised, and may be used in the form of pomades.—*Annales des Maladies de l'Oreille*, etc.

Physiological Action of Petroleum.—According to Dr. White, petroleum inhibits the growth of putrefactive and pathogenic bacteria, such as are met with in the alimentary canal, yet does not inhibit or interfere with the peptic or pancreatic digestion. It is therefore an agent for preventing flatulence, by relieving fermentation in such conditions of the bowels; in fact, it acts the part of an intestinal antiseptic. By its action in promoting peristalsis and increasing diffusibility of intestinal contents it helps the natural movement of the bowels and favors the elimination of noxious and toxic products from the system.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, August 9, 1902.

THE CAUSATION OF PHTHISIS.

LITERATURE regarding tuberculosis in all its phases has been so extensive during the past few years that the subject to some may appear to be becoming somewhat over-written and tiresome. Nevertheless, under existing circumstances, it is best that the matter should be kept before the public, and that the views of eminent men with regard to the causation of the disease should be widely distributed, in order that the opinions of Koch may be sifted as far as is possible.

Dr. Byrom Bramwell, physician to the Edinburgh Royal Infirmary, is one of the latest well-known authorities to propound his views. As to the nature and etiology of phthisis, he says the more important points to be considered are as follows:

1. All tuberculous affections are due to the introduction into the body of the tubercle bacillus or its spores; without the introduction into the body of the tubercle bacillus, or its spores, tuberculous disease is never developed.

2. Phthisis is always due to the introduction into the body of the tubercle bacillus or its spores, and the development in the lung of tubercles and the lesions which are associated with, and which result from, the development and growth of tuberculous lesions in the pulmonary tissues.

3. Phthisis may be either a primary or a secondary tuberculous lesion. In other words, in some cases of phthisis—and they constitute the majority of cases—the tuberculous affection of the lung is the primary tuberculous lesion; or to put it another way, in primary phthisis, the tuberculous lesion—which in its subsequent and later stages may affect many tissues and organs—is first developed in the lung, or in some part of the respiratory tract. In other cases the phthisis is a secondary tuberculous lesion.

4. So far as is known, the tubercle bacillus is never generated *de novo*, but is always derived from some previous case of tubercle, *i. e.* from a human being or from an animal, especially a bovine, affected with tubercle.

5. Tuberculous disease is conveyed from one human being to another by means of the secretions, excretions, and discharges which contain the tubercle bacillus or its spores; these discharges, more especially the sputum of phthisical patients, become dried and pulverized, and are inhaled in the form of dust with the inspired air. The sputum of phthisis is by far the most important source of infection, by which the tubercle bacillus is conveyed from one human being to another.

6. Further, if dust which contains the tubercle bacillus is capable of producing phthisis and other forms of tuberculous disease when introduced into the bodies of unaffected and susceptible persons, it follows that susceptible persons who inhabit the rooms and houses in which dust which is impregnated with the tubercle bacillus is allowed to remain and to accumulate run some risk of infection.

7. Tuberculous disease in the human subject may also be due to the introduction into the body of the tubercle bacillus or its spores derived from the lower animals, and especially from bovines affected with tubercle; in other words, tuberculous disease in the human subject may be due to the introduction into the gastrointestinal tract of tuberculous milk or tuberculous meat.

In the opinion of Dr. Bramwell, infection by tuberculous milk is a most important source of tuberculous disease, more especially of the mesenteric glands, and, therefore, of generalized tuberculosis and secondary tuberculous lesions in other organs and tissues, and consequently in the lungs, *i. e.* of secondary phthisis.

That a large amount of tuberculous disease in the human subject, and especially in young children, is due to the drinking of tuberculous milk, seems to be be shown by the facts that while the death rate from all forms of tuberculous disease, and especially from phthisis during the age-period from birth to five years, has, during the forty-five years from 1851 to 1896, markedly diminished in Great Britain, the death rate from tabes mesenterica has during the same age period diminished only 3 per cent., and below one year of age the mortality from tabes mesenterica has during the same period of time apparently increased by no less than 27.7 per cent.; and during the same period there has been a very large increase in the consumption of milk. Dr. Bramwell thinks that the danger of transmitting tuberculosis by means of tuberculous meat, while possible, is slight.

The opinions here expressed are in the main in harmony with those of other well-known investigators, except that Dr. Bramwell, together with nearly all British physicians, finds that secondary phthisis, presumably due to the ingestion of tuberculous milk, is much more prevalent in Great Britain than in any other country. The reason for this is not easy of explanation. It may be in some degree owing to the methods used in collecting statistics, or to the fact that the cows of Great Britain are more affected with tuberculosis than the dairy herds of other countries. It is notorious that less care is exercised in Great Britain than elsewhere in guarding cattle against the disease and in weeding out those already affected.

THE DIETETIC AND MEDICINAL VALUE OF ALCOHOL.

To the question whether alcohol is food or poison the answer may be given that the Celt made in the controversy as to whether the proper pronunciation was "nēther" or "nīther." "It is nāther," said he contemptuously. On the other hand, it may be found to be—paradoxical as it may seem—that alcohol is both food and poison, in accordance with the method and measure of its administration.

The matter has more than academic interest, inasmuch as the dietetic and medicinal employment or non-employment of alcohol must be based upon the decision arrived at. A most interesting discussion in connection with this subject was held recently before the Massachusetts Medical Society. In considering the nutritive value of alcohol, Professor Francis G. Benedict (*Boston Medical and Surgical Journal*, July 10), pointed out that this substance fulfills the requirements of a food in so far as it is readily and completely absorbed in the stomach; that when taken in moderate doses it is almost entirely oxidized within the body, thus constituting a source of heat; and that although it does not contribute directly to the formation of proteid and fat, it does, under certain circumstances, prevent the destruction of bodily proteid and fat. The danger of addiction should, however, never be left out of sight; while if taken in excess, alcohol not only causes gastric derangement, but also gives rise to toxic effects, and taken in moderate amounts there is reason to believe that it exerts a retarding influence upon many vital processes. Further, the dietetic value of alcohol is far behind that of a large number of other substances, so that its use as a food is entirely unnecessary in the condition of health, although under certain morbid conditions its ease of absorption and its high calorific value may outweigh its toxic effects.

In discussing the therapeutic uses of alcohol, Dr. Arthur R. Cushny indicated that this substance exerts a depressing effect on the central nervous system, primarily removing the influence of the inhibitory apparatus. Besides, mental and physical activity is lessened, both qualitatively and quantitatively. There are times, however, when precisely these effects are to be desired, and then of course, alcohol or some drug like it is to be prescribed. However administered, alcohol increases gastric secretion, and in this way it may promote digestion. To be useful as a food, alcohol would have to be taken in such large amounts as would cause cerebral symptoms in health, but might be tolerated under certain morbid conditions, as in the presence of high fever. A danger to be considered in the therapeutic use of alcohol is the formation of a habit.

In considering the influence of alcohol upon infection and the use of alcohol in the treatment of infectious diseases, Dr. S. J. Meltzer shows that, while in experimental observations on animals, alcohol, given in large doses at long intervals, fails to prevent, but rather to predispose to infection, in the presence of infectious disease in man, when given in smaller doses at short intervals, it has proved at least harmless, if not serviceable. A further difference between clinical and experimental observations is that in the former the infection is of gradual and in the latter of abrupt development, the organism being in the one instance given time to array its defensive forces against the invasion, while in the other it is not. Meltzer is inclined to consider the physiologic action of alcohol as stimulating, being expended especially on the inhibitory apparatus. Thus, the flushing of the face is to be attributed to stimulation of the vasodilators, or to inhibition of the vasomotor center. The general blood-pressure is not affected, but changes are brought about in the distribution of the blood, the dilatation of the peripheral vessels being compensated for by contraction of the splanchnic vessels. Whatever the explanation, however, evidence is not wanting as to the usefulness of alcohol in the presence of certain morbid conditions. Dr. Graham Lusk, in discussing the common use of alcohol as a beverage, pointed out the antiquity of this practice, and expressed the opinion that, taken in moderation, alcohol gives additional flavor to the food and acts as a mild narcotic, these effects being preceded by a period of exhilaration.

VACCINATION FROM ALL POINTS OF VIEW.

The *British Medical Journal* of July 5 is devoted almost wholly to a consideration of the vaccination question. The issue is splendidly set forth, and the various writers concerned in the discussion offer a strong defence of the efficacy of vaccination as a preventive of smallpox. The first part of the number deals with the life, work, and writings of Jenner, and gives, in a small space, the salient features of each.

Dr. Arthur Newsholme treats of the epidemiology of smallpox in the nineteenth century and reaches the following conclusions: "A careful study of statistics bearing on smallpox and of the different epidemics makes it clear that the chief governing factor is personal infection; that the disease spreads from town to town and from one country to another, not always affecting different countries in the same year, as it might be expected to do when similar climatic conditions occur in the different countries, if climatic conditions had a predominant influence. There is, however, some further factor responsible for the causation of the greater epidemics and pandemics of smallpox, which, for the lack of a better term, we must still designate by the old-fashioned name of "epidemic constitution." As the expression of a fact, without being committed to a theory, we may admit with the older epidemiologists that there is a constitution epidemica variolosa. What is meant by this is that at certain irregular intervals smallpox, as judged by its wider spread, is more infectious than it is in other years with equal opportunities for its dissemination. There is no regular periodicity for these greater epidemics, but there is a fairly regular periodicity for the minor epidemics in well-vaccinated communities.

Whether smallpox belongs to a group of diseases including scarlet fever, diphtheria, and rheumatic fever, which have been shown to become epidemic chiefly in years of deficient rainfall is open to doubt; but the statements already quoted on this point deserve fuller investigation than they have hitherto received.

In an article entitled "A Century of Vaccination," Dr. E. J. Edwardes shows that Germany is a striking example of the benefits derived from vaccination and revaccination at stated intervals, and that, as in the case of Bavaria, vaccination in infancy is insufficient to ward off attacks of smallpox after a certain period of time has elapsed.

Dr. F. R. Blaxall writes on glycerinated calf lymph, and with reference to the duration of its activity, says that this depends primarily upon the quality of the lymph when collected. A first-class lymph, glycerinated and kept under suitable conditions, may retain its full activity for a year or longer. An average lymph, however, cannot be depended upon to remain fully potent longer than two months, and one of inferior quality will become inert in still less time. It is in this respect of range of activity that the determination of the quality of the lymph at the outset is a matter of such importance. It must be understood that the human subject is, as far as is known, the most susceptible animal to vaccina, and that the transference of vaccine vesicles from the calf to the human subject, with or without glycerination, even if the calf vesicles are not of the first quality, will produce a human vaccinal manifestation typical in every respect, and therefore, in all probability, possessing full immunizing powers, provided that the calf lymph be used within its period of full activity. In calf lymphs of poor quality the duration of potency may be very short; in some cases hardly compatible with the complete effects of glycerination. Such lymphs need to be recognized at the outset and discarded.

The opponents of vaccination regard as the strongest weapon in their hands the assertion that the decrease, both in prevalence and virulence of smallpox is not due to vaccination, but to improved sanitation. Sanitation has undoubtedly had an important bearing upon the diminished smallpox rate, but so it has in a number of diseases, some of which, indeed, have been stamped out by such means. The methods used, however, to eradicate or control different diseases are not the same. Typhoid, typhus, diphtheria, and diarrhœa have been restrained by judicious sanitary measures, and doubtless so, to some extent, has smallbox, but the water supply or milk supply, or sewage or soil pollution has no special influence, so far as is known, upon the incidence or spread of smallpox. The article in the *British Medical Journal* demonstrates the truth of these points by statistics, and most assuredly shows that efficient vaccination is the greatest safeguard against smallpox.

American Views on the Treatment of Appendicitis.

The *London Hospital* of July 5 gives a short résumé of the opinions expressed on the treatment of appendicitis by American surgeons at the meeting of the American Medical Association this year.

Dr. John B. Deaver, and Dr. George G. Ross presented a paper giving a clinical review of a series of 426 cases. Out of the total number no fewer than 270 had been acute cases, and in these Dr. Deaver had a mortality of 15 per cent. The whole trend of this paper was in favor of early operation. The authors took strenuous exception to the general belief that amelioration of symptoms contraindicates operation, for all the miserable sequelæ of the disease could be avoided, they said, by early operation.

Dr. Parker Syms of New York held that in a series of fatal cases which he related death had in every instance been due to delay. Dr. Ernest La Place of Philadelphia said that an axiom with which everyone should be familiar was that at no time can any human being be sure of the extent of the disease, except after operation, and that therefore every case ought to be operated on at the earliest possible moment. Dr. Weir of New York agreed with Dr. Deaver that every case must be operated on at once. Dr. Murphy of Chicago said that the problem of when to operate was rapidly nearing solution. Practically all the members of the Section were agreed that it must be within thirty-six hours, and that when the profession became educated to this the mortality would be reduced to less than one-half per cent.

The *Hospital* does not agree with the American point of view of the treatment of appendicitis, and suggests that in a disease which shows such infinite variety, both in the nature and degree of the pathological changes existing, these attempts to ignore all differences in regard to treatment, and to bring down the whole business to one monotonous, dead level of operation are unwise. They appear, proceeds the writer in the *Hospital*, "to be the outcome of a sort of diagnostic despair, a hopelessness of ever being able to arrive at a satisfactory decision as to what cases may be safely left and what cases must of a certainty be operated upon; and notwithstanding all that is being said against what we suppose we may still call the English view, and especially against the cautious and judicious one taken by Mr. Treves, we cannot but feel that this view, which is based on the sound principle that different conditions call for different treatment, is the proper and the scientific one to accept in regard to this complicated question." It certainly must be something more than a coincidence that the majority of surgeons on this side of the water, with a remarkable unanimity, should have decided in favor of prompt operation in all cases of appendicitis. Undoubtedly American surgeons have had greater experience in the treatment of appendicitis than have the British surgeons, but, on the other hand, few have operated more often for the disease and with greater success than has Sir Frederick Treves.

The Betterment of London.

A Betterment of London Association has been inaugurated under the presidency of W. B. Richmond, the well-known artist, and who, it may be remembered, initiated some time ago a crusade against the smoke nuisance.

The principal objects of the newly-formed association are as follows:

1. To agitate for a quieter London, primarily in respect to unnecessary and objectionable street noises, such as those produced by organ-grinders, costermongers, and newsboys; for a healthier and cleaner London, obtainable by a constant removal of refuse and in other ways; and for a more clearly designated London. In this latter respect the association will direct attention, amongst other matters, to the illegible naming of public thoroughfares, and to the insufficient manner in which names are illuminated after dusk.

2. To agitate against the immigration of pauper aliens; against the employment—in the street—of children under ten years of age, and after nine o'clock P. M., of children under twelve years of age. To draw attention to the extreme danger to health engendered by the obnoxious habit of expectorating in public conveyances and buildings; to promote action against the sale of impure ice cream; to direct the attention of the authorities to the act relating to betting and gambling in public places; and to agitate against the constant digging up of the highways to the great inconvenience of the community.

3. To impress upon the municipal and other authorities of the metropolis the necessity of en-

forcing, as in Liverpool, the registration of street "musicians" and street traders, including newspaper venders, and to impress upon the railway companies the desirability of freeing their stations and approaches from all idlers and hawkers.

It seems a pity that there is no Mr. Richmond in New York to form an association for the betterment of New York, for if the former city needs improvements in the items mentioned, the same conditions are rampant in New York in an intensified form. What a boon to the community at large would be a quieter New York, and if such a blissful state of affairs could be brought about, how the nervous complaints to which its inhabitants are so subject would diminish. With regard to the refuse in the streets, and particularly to the household garbage, the metropolis of the United States is in the same malodorous condition as that of the British Empire. It is a common sight in New York to see the garbage wagons slowly proceeding along respectable residential streets on the afternoon of a sultry day, picking up their unsavory burdens, and leaving a scent in their wake the reverse of pleasant.

As to the designation of street names, it may be asserted without fear of contradiction, that in no city of the civilized world does so disgraceful a state of things in this respect exist as in New York at the present time. There are miles of streets whose numbers are lacking—a source of boundless inconvenience to the stranger within her gates.

The employment of children of tender years on the streets, and especially after dark, is equally bad in both cities, and if the lighting of London is worse than that of New York it must be vile indeed.

Public opinion, stoutly expressed, would have the effect of remedying the evils above mentioned, and the sooner such a course is pursued the better will it be for the inhabitants at large.

MEASURING SLEEP.

The phenomena of sleep have always possessed a peculiar interest for scientific men. Shakespeare not inaptly called sleep the twin sister of death, and philosophers of every age have racked their brains in investigating its mysteries.

The *New York Tribune* of July 20 discusses the matter and gives the result of some researches on the subject recently made by Italian students. It has long been known that age, sex, occupation, and state of health influence the period of unconsciousness termed sleep, and also the soundness of sleep. Again, it has been thought that sleep is variable with every individual, although slumber may be practically unbroken. The fluctuations of the depth of sleep have been the object of the investigations of Dr. Sante de Sanctis and Dr. D. Neyroz of the University of Rome, who have conducted a series of experiments extending over six months. Nine persons, four of whom were thoroughly healthy, and five of whom had diseased nervous systems, were selected as the subjects of these tests. The general plan of procedure was to wait until they had fallen asleep, and then to employ uniform means to awaken them.

An instrument named the æsthesiometer was used for this purpose. The essential parts of the sleep measurer were a blunt point to be pressed against the skin, a spiral spring, and a carefully-graduated scale, which showed the degrees of pressure used. The point was gently applied to the sleeper's left temple, and pressed until he awoke, when the scale was examined and notes were made of the hour and minute, and of the scale-reading. The same person was not awakened more than once or twice a night, but the experiments were so timed that in the course of a few months they covered the whole eight-hour period during which sleep lasted, at intervals of ten or fifteen minutes several times over.

The result of these experiments showed that the soundest sleep in the four healthy subjects occurred between an hour and a quarter and an hour and a half after lapsing into unconsciousness. During this period unconsciousness rapidly and almost steadily increased, and then in the next quarter of an hour greatly diminished. Thereafter surprising oscillations were detected on the average, though the stages of lightest sleep occurred about four and a half and again five and a half hours from the beginning. A short, low, secondary maximum of intensity followed in the next hour and a half or two hours. From this point the decline was rapid to the final awakening. In those of diseased nervous systems, epileptics and paralytics, very much the same state of things was observed, except that they slept more profoundly than the healthy subjects, and in one person the unconsciousness at the end of fifteen minutes was almost as marked as at an hour and a half.

THE DEADLY AUTOMOBILE.

The urban population of the United States taken in the mass are heartily sick of the manner in which automobilists are permitted flagrantly to break the law, and to endanger the lives and limbs of peaceable citizens. It would almost seem as if driving an automobile had an injurious effect on the brain, and rendered its votaries more or less irresponsible for their actions. Perhaps the exhilarating influence of rushing along at great speed and the feeling of the driver that he is in control of a force tends temporarily to unbalance his mind and to make him careless of consequences. Certain it is that for the most part motor carriages are driven in cities with a seeming disregard for the rights and safety of others that is absolutely brutal and to which a stop should be promptly put.

Mr. Louis Windmüller, a recognized authority on the subject, writing in the spring number of *Municipal Affairs*, has this to say: "Ordinances which restrict their speed to eight miles an hour in cities are seldom heeded. The most flagrant violations rarely are punished with adequate severity. Gliding noiselessly and swiftly over smooth pavements, these vehicles are apt to run down the unfortunate who may cross their paths. In turning corners they seldom reduce speed to the rate ordained by the law. Frequently they collide before they can signal their approach. The cyclist on such occasions is apt to suffer with the pedestrian, and consequently is more careful than the chaffeur, who relies on the superior strength of his vehicle."

Though perhaps the New York chaffeurs do not equal those of Paris in impudence and indifference to the rights of others, yet they are bad enough. Upon any day one may witness automobiles being driven up and down Fifth avenue at a rate of from ten to thirty miles an hour, while the guardians of the peace watch their comet-like course with an "it's-no-business-of-mine kind of look." If it is found impossible to restrain furious driving of horseless vehicles in cities, they should be kept off the streets entirely and restricted to enclosed roads of their own. Public sentiment will soon ordain that steps be taken to abate the automobile nuisance.

News of the Week.

Columbia Fellowships for Post-Graduate Study in France. President Butler of Columbia University some time ago addressed a communication to the Minister of Public Instruction in France, proposing that arrangements should be entered into for the establishment of several international fellowships which should encourage American students to pass a portion of their period of advanced study in France, and *vice versa*. It is proposed that Columbia University shall establish two annual fellowships of a value of $1,200 each, the holders of which shall carry on their studies at one or more of the French universities. In return, it is proposed that the French government shall establish two fellowships of equal annual value, the holders of which shall carry on their studies for a year at Columbia University. The fellowships are to be open to graduate students only, and the holders of them will be chosen in a manner precisely similar to that in which the university fellowships at Columbia are now awarded. Graduate students of law and medicine will be permitted to compete for these fellowships on equal terms with those who have taken the degree in arts.

The Cranium of Leibnitz.— Prof. Waldeyer read a paper recently before the Academy of Sciences in Berlin giving an account of the examination of the skull of Gottfried Wilhelm Leibnitz, the philosopher, who died in 1716. An estimate of the brain weight founded upon measurements of the cranial capacity gave only 1,257 grams. This is unusually small, the average weight of the European brain being 1,367 grams.

Remarkable Fecundity.—A Valencia journal reports the case of a woman forty-four years of age who, in the twenty-four years of her married life, has given birth to twenty-four children, all born alive and healthy at full term and all single births. One physician, Dr. Llabrés, has assisted at the delivery of nineteen of the twenty-four children, and says that he sees nothing in the woman's condition to lead him to fear that his occupation as annual accoucher will be terminated for several years to come.

An Aged Physician.—Dr. Henry Helfrich of Allentown, Pa., celebrated, on July 22, the ninety-ninth anniversary of his birth. He is the oldest resident of the city, and in all probability the oldest physician in the State.

The New York State Hospital for Consumptives.—The commission in charge of the construction and maintenance of the proposed State hospital for consumptives to be located in the Adirondacks, met in Albany on July 30 and approved the plans for a two-story brick and stone building, to be constructed on the pavilion plan with an administration building in the center. The hospital is to accommodate a hundred patients, and is to be located at Raybrook, Essex County, between Lake Placid and Saranac. It is to be started under the appropriation of $100,000 made by the Legislature, it being the expectation that work can be begun this fall, so as to have the building ready for occupancy next year.

Ophthalmia in the Public Schools.—In a recent communication to the Board of Education, Dr. Lederle, the Commissioner of Health, said that eye diseases, especially trachoma, had increased alarmingly among the children of the public schools, and he asked that a room be set apart in each school for the use of physicians appointed by the Board of Health to examine the children's eyes. Dr. Lederle said that during the last two weeks of the school year twelve ophthalmologists had examined 55,000 children in thirty-six schools and no less than 6,670 children, or 12 per cent., were found to be afflicted with contagious eye diseases. Of this number 2,328 were suffering from trachoma.

Microbes in the Streets.—Dr. Woodbury, Commissioner of Street Cleaning in this city, recently undertook to determine the number and kind of microorganisms floating in the atmosphere of the town. A number of gelatin plates were prepared and exposed for a time at different levels above the street in various parts of the town. The result was unsatisfactory—not because no microbes were found, but because there were so many that the plates were simply a mass of colonies so thickly crowded together that it was impossible to distinguish them. Other experiments are now being made with briefer exposure of the plates.

Professor Virchow Ill. It is reported from Berlin that Prof. Rudolph Virchow has had another severe fall, and is now dangerously ill in consequence thereof. His first fall took place about the middle of last January, but he made a satisfactory recovery and was doing well until this second mishap occurred. He will be eighty-one years old in October.

An Army Post for Convalescents.—A new army post is to be established at Monterey, Cal., the increase of troops in California having made more barracks necessary. Owing to the excellent sanitary situation the Monterey post will be used as a station for soldiers returning from hard service in the Philippines and for convalescents.

Ambulance Cars on German Railways.—The Berlin correspondent of the *New York Times* says that the German State railway administration has decided to maintain ambulance cars at seventy-seven of the principal stations throughout the country. The cars will contain a full hospital equipment, including operating tables and beds, calculated particularly to render everything necessary in the direction of first relief. Each car is to be in charge of a medical officer, while all railway employees will be required to be trained in the performance of first-aid duties. The cars will be so located that none will be more than an hour and a half away from a hospital, thus rendering quick transportation for victims who require serious attention. Within the past year there has been an unusual number of railway fatalities in Germany due to the inaccessibility of medical facilities.

Cholera.—The efforts of the sanitary authorities in the Philippines to suppress the cholera epidemic have been materially aided by typhoons. A second typhoon of the season visited the islands the last two days of July and cleansed Manila thoroughly. The sea was forced into the canals and flooded the districts where cholera has been raging. The result was that there were only twenty-five deaths from the disease on July 31, and the number of new cases was geatly reduced.

Dr. E. J. Gardiner has been appointed professor of ophthalmology at the Chicago Eye, Ear, Nose and Throat College.

Smallpox is reported to be prevailing very extensively in several parts of New York State and Pennsylvania, especially in the neighborhood of Geneva, N. Y., and in Delaware and Lancaster counties, Pa. The spread of the disease is said to have been greatly favored by several negro camp meetings, and one at Collingswood was for this reason broken up by the Borough Board of Health. In New York City, on the other hand, there were but three cases of smallpox during the week ending August 2, which is the lowest record for any week since the outbreak began in November, 1900.

Practical Experience Necessary for German Physicians.—According to a recent law enacted in Germany, permission to practise medicine in that country will be given only to those who have passed at least one year in practical work as assistant to some physician approved by the Imperial Chancellor, or in a hospital or university klinik, devoting no less than four months entirely to internal medicine. In addition to this the usual Staats Examen must be passed by the would-be practitioner.

King Edward's Health.—It is stated in the London *Daily Mail* that the King's surgeons do not contemplate the necessity of a second operation, and it is believed that he is well on the road to permanent recovery without any further surgical treatment.

The Rocky Mountain Inter-State Medical Association will hold its next meeting at Cheyenne, Wyo., on September 9 and 10, under the presidency of Dr. R. Harvey Reed of Rock Springs, Wyo. The corresponding secretary of the association is Dr. S. D. Hopkins of Denver.

A Milk Exposition.—There will be held in Hamburg on May 2-10, 1903, an exposition of Hygienic Milk Supplies. Every phase of milk provision, from the selection and care of the cow to the methods of keeping milk in the house, will receive attention. In connection with the exposition there will be a series of addresses and papers by dairymen, sanitarians, and physicians on milk in all its aspects as an article of commerce, as a food, and as a therapeutic agent. Details of the exposition may be obtained by those interested by addressing Herr Oekonomierath Boysen, Kampstrasse 46, Hamburg 6, Germany.

Sanatoria in New Mexico.—Silver City, N. M., promises to become known as the home of sanatoria. The establishment of the United States Army Hospital at Fort Bayard directed attention to the climatic advantages of that country, and soon thereafter the Sisters of Mercy founded St. Joseph's Sanatorium under the care of Dr. Earl S. Bullock, formerly bacteriologist at Fort Bayard. A new wing has just been added to St. Joseph's, and it is intended soon to build a number of cottages for the use of patients accompanied by their relatives. In addition to this a new sanatarium is projected; the Timmer House in Silver City, having been purchased for that purpose, will be converted into a modern hospital building.

The Prevention of Tuberculosis.—The Charity Organization Society's Committee on the Prevention of Tuberculosis needs not less than $10,000 to meet the expenses of the work which it has undertaken. Contributions made to the Society for its usual current operations cannot be diverted in any large amount to the purposes of this Special Committee. The expenditures to be made by the Committee are for the following main objects: (1) Research into the social—as distinct from the medical—aspects of tuberculosis—for example, into the relations between the disease and overcrowding, infected tenements and unhealthy occupations, and also into the influence of improved diet and hygienic living upon recovery; (2) Education. The publication of leaflets and pamphlets, the giving of lectures, and the promulgation in every possible way of the fact that tuberculosis is a communicable and preventable disease; the widest distribution of the resutls of scientific research in this field, and of the results of modern treatment both in sanatoria and at home; (3) The encouragement of movements for suitable public and private sanatoria, both for advanced and for incipient cases; for adults and for children; for free care, and also for the care of those who can pay moderate fees; (4) The relief of indigent consumptives by the provision of suitable food and medicines, by the payment of rent when this is necessary to secure adequate light and air, and by transportation and maintenance at a distance when in the judgment of the committee this is essential. Contributions may be sent to the Committee, care of the Charity Organization Society, 105 East Twenty-second Street, New York City.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HOSPITAL FUNDS—A MEDICAL SERVICE OF INTERCESSION—LEPROSY DISCUSSION — PROFESSOR M'ADAM'S TRAGIC DEATH—STAFF COLLEGE—R. C. S. ELECTION—DEATH OF DR. WASHBOURN, C.M.G.

London, July 10.

The King's Hospital Fund is not likely to suffer through his Majesty's illness. You know that it was proposed to augment it by a coronation gift from the people to their King. The organizing committee were very active; no charity has been more advertised, and the advertising has cost little, being so largely done by the contributors of the newspapers. On June 9 some £55,000 had been acknowledged, and it was hoped £100,000 would be subscribed before the coronation.

Among many suggestions now made the most notable is that the intended coronation gift shall be a "thanks offering" for the King's recovery. If a coronation should, after a time, take place, of course that would be the time to present the gift. Until it is actually presented it is not intended to make a final announcement of the amount received.

A "medical service of intercession for the recovery of the King" was held in St. Paul's Cathedral on Wednesday evening. It was organized by the council of the Guild of St. Luke, and what these gentlemen mean by a medical service is one for medical men to attend, but, of course, conducted by the clergy. In the invitation they said it was intended to be representative of the whole profession, and not peculiar to the Guild of St. Luke, but in order to make it a "public corporate act of intercession on behalf of the profession," they hoped all who could would "wear academical robes," and they kindly made arrangements for robing. This guild has always attached great importance to a display of academical costumes—as much, in fact, as the high church clergy, from which it sprang. But the profession cares nothing about clothes—or, begging the guild's pardon—robes. Nevertheless, the service was an interesting one, and the robes lent a dash of color to the scene.

The important discussion on leprosy at the Royal Medical and Chirurgical Society showed a tolerably general opinion against the fish theory still held by Mr. Jonathan Hutchinson, though he has been compelled to admit contagion as an additional factor, as you may have noticed in the abstract of his paper which I sent you. Mr. Tonkin's paper did not give rise to much criticism; it could hardly do so as it dealt with the facts within his experience, and supported the more general opinion. In his reply he said fish was seldom consumed in Nigeria, and it was rarely to be met with in the markets of the natives.

Dr. Hansen of Bergen who opened the discussion on the two papers said he believed that leprosy was solely propagated by contagion. He held it to be a specific disease with a specific course, and gave instances which at first seemed hereditary were later proved to be due to contagion. The bacillus could be cultivated, though with difficulty. If it could exist in salted fish it ought to be easy to cultivate in artificial media.

His experience in Norway confirmed his opinion. There the people are now eating fish just as they used to do, but the disease is disappearing. Since 1856, lepers in Norway had been isolated, and from that time there had been a steady decline from the 2,870 lepers, then known, to about 400 which now remain. None of the Norwegian emigrants to America had developed leprosy—a fact against the hereditary theory. As to the *de novo* hypothesis the disease might be latent for years, though capable all the time of inspection. The rate of development was very slow, the irritation caused by the bacillus was very slight and might be quite overlooked. It probably entered by the skin, any abrasion affording it full opportunity.

Dr. Thin cited Dr. Benson's case as proving contagion. Several years after the patient's death his brother developed the disease. The two had slept in the same bed, worn the same clothes, and used the same eating utensils. This was no isolated instance. When he was in China the idea of food contagion had occurred to him, but he found it untenable. In one of the papers under discussion lack of animal food was blamed; in the other excess of nitrogenous food.

The Royal Commission had reported that the disease was propagated independently of fish or any other food. The bacillus caused so little irritation that its entrance would not be observed, and even microscopically there were very few signs of inflammation. As to the *de novo* hypothesis it would involve a *de novo* origin of the bacillus also. The disease had been known in Egypt longer than anywhere, so Africa should be the last place to look for *de novo* cases.

Dr. P. Manson said he was a contagionist, though we know nothing of the exact mode of spreading. He compared the disease to tuberculosis. Ainhum had been thought to be a manifestation of leprosy, but this was not so in his experience. In many cases the early lesions were not symmetrical, and there seemed no evidence of a constitutional disease. He had heard that the bacillus had been cultivated in fish-broth in Ceylon. Malarial infection was through the skin; probably the large parasite of ankylostomiasis entered through the same channel; so the minute leprosy bacillus might find no difficulty. He thought Mr. Tonkin's suggestion very probably the true explanation in the Soudan.

Sir. W. Kynsey said dried fish was universally used in the interior of Ceylon, where leprosy was almost unknown, though it occurred in certain places along the coast where fresh fish was obtainable.

Sir Lauder Brunton had seen a number of cases in Jerusalem which resembled syphilis, and suggested a mixed infection. Unna had given large quantities of hydrochloric acid to make the blood less alkaline, but this result could be attained by a more highly nitrogenized diet.

Dr. T. M. Young, who has seen leprosy in India, China, and Africa, remarked on the great motility of the bacillus, suggesting a life history outside the human body, as in the malaria organisms. He found the bacilli more numerous in the deeper living tissues than in the leprous sores. He did not find fish eating to correspond with leprosy distribution.

Dr. Heron, who served on a committee ten years ago with Mr. Hutchinson, rejected the fish hypothesis. The test should be finding the bacilli in dried fish in the laboratory. The report of the commission said out of 464 lepers 99 had never tasted fish; 162 lepers in asylums scattered all over India had not eaten fish; some who came from high up the Himalayas had never seen fish.

Dr. A. Hillier, who has seen leprosy in both North and South Africa, asked if salt fish conveyed leprosy, why not fresh fish? That a leper had not seen another was of little import, as the disease was so easily overlooked. A case in support was cited. Eating salt fish is common enough in England, but we have no leprosy, which vanishes all over the world with the spread of sanitation.

Mr. Hutchinson, in reply, adhered to his views, and said he lived in daily expectation of the bacillus being discovered in fish, which, he admitted is the crucial test of the theory.

A shocking tragedy took place last week in the Edinburgh College of Surgeons. Mr. W. I. McAdam, professor of chemistry, was engaged in his laboratory when a porter, apparently in a fit of sudden madness, walked in with a rifle and shot him dead. An assistant, Mr. Jas. Forbes, ran to the telephone to give the alarm, and was also shot. Other men present scattered, except Dr. Stevenson McAdam, brother of the first victim, who went up to the maniac and spoke to him, eventually persuading him to hand over the rifle, and then seizing him and holding him until the police arrived. The deceased professor was to have started for London about that time, and soon after the tragedy his son and two of his daughters called, as they were to accompany him. Naturally, they were prostrated at discovering what had occurred.

The proposal to establish a staff college for the R.A.M.C. in London has been approved by the War Office, and the next session of the Army Medical School is to be held in the laboratories of the two colleges on the embankment instead of at Netley.

The Duke of Connaught laid the foundation-stone of additional buildings to Charing Cross Hospital, with full Masonic ceremony, last Friday, and named a new ward "Louise Ward" after his sister. The mallet used was the one used by Charles II in laying the foundation stone of St. Paul's Cathedral and presented by Sir Christopher Wren to a Masonic lodge, by which it was lent for this ceremony.

Dr. J. W. Washbourn, C.M.G., Physician to Guy's Hospital, died on the 20th inst. He was only thirty-eight years old, and yet had achieved a great reputation. You will know him best, perhaps, as a bacteriologist, but he had a firm grasp of pathology and medicine in their extensive relations. He was also physician to the Fever Hospital. His career as a student and physician was exceptionally brilliant throughout. He acted as consulting physician to the Imperial Yeomanry Hospital in South Africa, 1900 and 1901, where his services were much appreciated. He was mentioned in despatches and received the C.M.G. for his services.

Boston Medical and Surgical Journal, July 31, 1902.

Non-Operative Head Injuries: Diagnosis and Treatment.—T. J. Robinson gives directions in detail for the diagnosis and treatment of injuries to the scalp, certain forms of vertex fractures, fractures of the base, cerebral concussion and contusion, certain cases of compression, and certain cases of laceration, in all of which no operation on the skull or its contents is found to be advisable. In conclusion he urges the importance of two things: (1) Extreme and immediate care in the antiseptic treatment of all wounds and abrasions of the soft parts of whatever degree; (2) Extreme care in the feeding and general nursing. By attention to these points can septic and pulmonary complications best be avoided, and the patient be given his best chance.

Indications for Operation in Head Injuries.—Edwin Willes Dwight says that personal experience and a study of all the cases that are available, have apparently demonstrated that the symptoms presented in the majority of cases of injury to the brain are ill-defined, and not such as we might expect from a study of the literature; that they are best defined in those cases that are least apt to be benefited by operation; that in the vast majority of all cases of injury to the brain, and especially in those such as one-sided extradural or subdural hemorrhages, where an operation may be expected to give relief, the symptoms are indefinite and may be entirely wanting. He lays down the following rules: Given positive signs of intracranial disturbance following an accident which might well cause such a condition, but without definite signs of fracture—explore. Given a case in which there is probable evidence of fracture, and a probability of interference with the brain—operate. He has never seen fatal or serious results follow trephining by skilful hands, even when two or three openings in the skull were made, and he has seen many lives saved by exploratory operations in this large class of doubtful head injuries.

Indications for Operation in Head Injuries.—William N. Bullard would operate in all cases of compound depressed and compound comminuted fracture of the cranium. Simple fracture of the cranium does not, as a rule, demand operation. Absence of unconsciousness does not contraindicate operation. If unconsciousness last more than twenty-four hours, no other cause than the injury being present, operation should be considered. Marked rise of temperature after uncomplicated head injury suggests injury to the brain; but is not necessarily an indication for operation. Sub-normal temperature with unconsciousness lasting twenty-four hours or more suggests œdema of the brain or intracranial hemorrhage. Severe pain in the head continuing for some time after a head injury, if organic, indicates operation. It may be functional and due to general nervous conditions. Clonic and diffuse convulsions suggest epilepsy or other complications. When localized they indicate the side of the brain on which the lesion producing them is situated. Taken in connection with other symptoms their presence usually favors operation. Marked paralysis of the limbs *in adults* usually indicates immediate operation. Partial hemiplegias and paralysis of the limbs may occur in œdema of the brain following injuries.

Journal of the American Medical Association, August 2, 1902.

Acute Gastroenteritis or Summer Diarrhœa of Infants.—Margaret Taylor Shutt says that if the child vomits repeatedly, washing out the stomach a single time will usually afford relief; if not, minute doses of calomel will in many cases allay the gastric irritation, clear out the intestinal tract, and act as a powerful intestinal antiseptic. When the stools are small and offensive, flushing out the colon is of great value, and is worth while even if done only once. If there is no nausea, castor oil must be given immediately after, otherwise 1-10 gr. doses of calomel hourly. Milk must be stopped at once, only cold boiled water being given for twelve hours, then a liquid preparation of beef peptonoid. Care-takers should be impressed with the fact that the disease is an infectious one, and that the discharges must be disinfected, the napkins boiled before using again, and hands thoroughly cleansed.

A Comparative Study of the Attachment of the Teeth.—Frederick B. Noyes says that the fact that the teeth are not a part of the osseus system, but appendages of the skin, supported in man by a special development of bone forming the alveolar ridges of the maxillary bones, is as well established as any fact concerning human dentition. The author takes up the four forms of attachment as given by Jones: (1) By fibrous membrane; (2) By hinge joint; (3) By ankylosis; (4) By insertion in a socket, and shows the comparison between them, and the evolution of the more complicated forms from the simpler. In the simplest teeth, those of the shark lamna, there is no development or modification of the arch of the jaw, and the teeth have no direct attachment to the bone—in fact, the jaws themselves are chiefly cartilage. Hinged teeth are found in many fishes, and in the poison fangs of the snakes. Ankylosis is confined to the teeth of bony fishes. The development of socket implantation is associated with great increase in the size of the teeth, and consequent necessity for stronger attachment.

Evolution of the Pulp.—Eugene S. Talbot says that in each order up to the primates occurs a difference in the size of the dental foramina, showing a struggle for existence between the orders. In the evolution of the pulp from the placoid scales, the pulps are often many times larger than the scale. Sauropsidæan pulps are generally as large, and sometimes larger, than the tooth. Shark teeth from their groove type have large pulps. The formation of projections in the grooves of toothed birds and in some mammals show where changes from open sockets to closed foramina of the teeth occur. The varieties which produce the toothless birds, the ornithorhyncus and the baleen whale to the lower dental types indicate that degeneracy in an organ which is for the temporary benefit of the type as a whole. The persistency of open pulps at the expense of the tooth as a complete type is an indication in the same direction. When the dental blood supply is cut off, and nourishment ceases, from the closing of the foramina in man, and some lower vertebrates teeth virtually become foreign bodies. Decay is therefore a natural process of excretion. Since blood does not reach the enamel and dentini, and nutrition is cut off, tooth decay is controlled by the trophic nervous system. The pulp is, hence, still a transitory structure in human evolution, and one on which nervous and metabolic storm and stress exerts a strong play.

Medical News, August 2, 1902.

Dextrocardia Due to Pulmonary Cirrhosis, with Presentation of Case.—Henry Levien gives a brief description of a case of cirrhosis of the right lung complicated by a cavity of considerable size in the middle lobe anteriorly. The heart was drawn to the right side, showing the apex beat in the fourth intercostal space about half an inch to the right of the sternum. The heart's action and pulse were normal; cardiac dyspnœa was absent. No displacements of other organs were found. The sputum contained tubercle bacilli.

Carcinoma Limited to the Appendix Vermiformis.—Richard H. Harte and Robert N. Willson discuss at length the question of primary carcinoma of the vermiform appendix as a cause of appendicitis and report two illustrative cases, both of which were operated on successfully. The total number of recorded cases in which the appendix has appeared to be primarily involved by a carcinomatous growth is still extremely small—in the neighborhood of thirty—and those in which the growth appears to have been limited to the organ, comprise a still smaller number. The authors reject the theory of a parasitic origin of the carcinoma, and believe that the original focus was a catarrhal inflammation, probably due to fecal or other obstruction, or to extension from the bowel, and that the carcinomatous change took place subsequently to, and entirely as the outgrowth of the former process. If the appendix be removed while the growth is still limited to that organ, a recurrence should not take place.

The Modern Treatment of Pterygium.—F. B. Loring describes the new and simple operation devised by Dr. A. Coe of Washington, and performed by himself with complete success in twenty-two cases. The only instruments required are an alcohol lamp and a platinum wire, mounted on a wooden handle and having a hook about three and a half millimeters in width and one in thickness. After the eye is thoroughly cocainized, he presses the bottom of the convexity heated to a white heat against the point at which the apex protrudes above the surface of the cornea, on the pupillary side, and then, elevating the handle, brings the rest of the platinum to bear in a direction parallel to the axis of the pterygium from the apex toward the base. One application of the cautery, if thoroughly done, is generally sufficient. It has been the author's habit to put the eye through a preliminary course of treatment with Pagenstecher's ointment to reduce the vascularity and to decrease the size of the growth as far as possible before operating.

American Medicine, August 2, 1902.

Should the Tampon Be Used in Postpartum Hemorrhage?—J. F. Baldwin considers the control of postpartum hemorrhage by the tampon contrary to physiology, to physics, and to all surgical principles. He does not believe that by the introduction of gauze into the full-term uterus sufficient pressure can be exerted to arrest the bleeding or that a tampon of the proper size can remain aseptic while being passed through the vulvar orifice and vaginal canal.

A More Rational Method of Passing the Suture in Fixation of the Kidney.—Max Brödel proposes a method of fixation of the kidney which prevents the tearing out of the simple through-and-through sutures generally employed. The principle of this new suture, which is applicable not only to the kidney, but to any other friable organ, is as follows: (1) The direction of the suture is not parallel to the framework of the cortex, but at right angles to it; (2) The fibrous capsule, being the most resistant structure, is utilized instead of the kidney substance itself to furnish the main support for the suture; (3) The suture is passed in a triangular manner through the cortex, so as to have two suture bridges on the surface of the kidney. These bridges bear the brunt of the work, and traction on the suture is borne by them instead of by the circulatory or secretory structures of the kidney. To make this suture tear, the bridge must pull the fibrous capsule into the cortical substance of the kidney, a procedure requiring considerable force.

The Significance of Post-operative Pleurisy; Its Relation to Pulmonary Embolism.—G. Brown Miller, from a study of the histories of sixteen cases of post-operative pleurisy recorded in the gynecological department of the Johns Hopkins Hospital, finds that in at least one-half of the cases the pleurisy had its origin in a pulmonary embolus, and was probably the result of infarction of the lung. Phlebitis or thrombosis of the crural vein, some of its branches, or one of the pelvic veins, was in most of these cases the apparent source of the embolus. The statistics of various authors show that pleurisy is, in a certain number of cases, the result of a pulmonary embolus. This is especially true in that form of the disease which occurs after operation or labor, coming on suddenly with sharp pain in the chest, dyspnœa, which is of limited extent and without known cause. In such cases one should bear in mind the possibility of the occurence of a fatal pulmonary embolism of which the first is a precursor, and take precautions to prevent any unnecessary muscular movement of the patient until the danger of embolism is past.

The New York Medical Journal, August 2, 1902.

Malarial Origin of Zoster.—James MacFarlane Winfield, who, in 1895, gave the results of examinations of the blood in eight zoster patients, showing that about 50 per cent. of them were suffering from malarial infection, now reports twenty-five additional cases, all of which had symptoms suggestive of some infection, and fourteen of which gave positive evidences of paludism as proved by the presence of the malarial parasite in the blood. The author states that while it is not his intention to assert that this special organism is the only causative agent in the production of this neurocutaneous disorder, zoster (for it is undoubtedly that many different varieties of bacterial intoxication could bring about the same effect), he maintains that the plasmodium malariæ should be considered one of the causes in a disease that is so etiologically uncertain.

Some of the Therapeutic Uses of the X-Ray.—E. D. Bondurant reports a case in which the use of the *x*-ray completely relieved the pain of a carcinoma of the face, caused a cessation of discharge and the formation of healthy granulations, the present condition being that of a fairly healthy ulcer, which is steadily healing. In a second case there is apparent cure of an epithelioma of the face; in a third the progress is extremely satisfactory after only eleven treatments; and in a case of lupus, the nodules are shrinking and the ulcerated surface is healing after ten sittings. A specific effect in relieving pain has been attributed to the *x*-ray, with ample confirmatory evidence. It has a remarkable influence in stopping the pain of carcinomatous growths, and the author has known it to cure facial and intercostal neuralgia, headache, and functional nerve pains. The permanence of the cures of epithelioma, lupus, etc., can be demonstrated only by time. Recurrences have thus far been infrequent, but not unknown. The advantages possessed by the *x*-ray treatment are certainty of good result in suitable cases; the inconspicuous scar and absence of subsequent contraction in the scar tissue; absence of pain, and entire absence of danger.

Philadelphia Medical Journal, August 2, 1902.

A Case of Albumosuria of the Pernicious Anæmia Type.—Herman F. Vickery describes a fatal case of albumosuria occurring in a male patient of middle age; the examination of whose blood revealed a condition found in pernicious anæmia. Temperature, pulse and respiration were but slightly altered. The patient did not complain of his bony framework in any way, and nothing abnormal was detected upon examination. The *x*-rays revealed a slight dilatation of the heart and of the aorta, but no abnormalities in the bones. No autopsy could be obtained.

Cocaine as a Thermogenic; Its Modes of Action.—Edward T. Reichert's experimental research has demonstrated the following facts: (1) That the rise of temperature caused by cocaine is due to an increase of heat production, and that the latter depends upon two actions—one upon the cortex, causing motor excitement, and the other upon the caudals thermogenic center, by which heat is produced independently of motor activity; (2) That cocaine possesses very little power as a thermogenic in animals lightly curarized, because of both the motor quietude and the depression of some other portion of the thermogenic apparatus; (3) That cocaine is absolutely without thermogenic power in animals in which the pathways of thermogenic and corticospinal motor fibers have been cut, as after sections of the spinal cord at its junction with the bulb and of crura cerebri; (4) That cocaine is effective as a thermogenic when only a small portion of the caudate center is left intact with the parts below; (5) That cocaine and morphine are direct antagonists in their actions upon the caudate and cortical centers which are directly or indirectly involved in the changes of temperature and heat production.

The Lancet, July 26, 1902.

Injuries of Nerves.—In his second lecture on this subject, Anthony A. Bowlby says that of the chief causes of failure in secondary suture of a nerve, the first is sepsis, and the second the lapse of time between the reception of the wound and the operation. Nerves unite differently, so far as utility of the part is concerned. For instance, a navvy may have his hand restored to all the sensation and power necessary for his work, whereas a cabinetmaker, or a pianist or a violinist, for whose work it is essential that sensation and minute movements in every part of the small muscles of the hands should be as complete and natural as possible, will not have so satisfactory a result. Sometimes nerve ends are so far separated that they cannot be approximated, in which case nerve grafting will have to be resorted to. Partially divided nerves do not, as a rule, need to be operated on.

Note on a Case of True Intestinal Sand.—Charles H. Bedford reports the case of a woman of forty-four years with a marked history of gout. There was complete absence of painful paroxysms, vomiting, and flatulence. At the time the sand was passed she had been for months on a milk and farinaceous diet. An analysis of the deposit showed: moisture, 5.20 per cent.; calcium phosphates, 28.68 per cent.; calcium carbonate, 5.20 per cent.; magnesium phosphate, 0.49 per cent., and organic matter, 60.43 per cent. No trace of urates or uric acid. This clearly shows that the case was one of true intestinal sand, as distinguished from the "false," which owes its origin to undigested vegetable particles. The cause is obscure, and all that can be said at present is that the condition would appear to be very closely related to gout, and to be favored by a milk diet.

Puerperal Aphasia.—M. A. McIntyre Sinclair gives an analysis of eighteen cases of this disease. Poupon considers that they may belong to one of two classes: (1) Those due to nervous origin, and (2) those due to vascular origin. The author admits the occurrence of cases due to a nervous dyscrasia, such as hysteria or reflex disturbance, otherwise he thinks that many cases are attributed to this class which are really of vascular origin. As to the second class, some cases may be due to cerebral thrombosis or embolism. In many cases, however, there is no evidence of degenerative changes of the blood vessels, no cardiac disease, no albuminuria, and no suspicion of neurotic habit. The key to the situation lies in the composition of the blood itself, and the greater tendency which puerperal women have to the formation of clots within the vessels. The author enters into this point in detail, and quotes from the literature and from clinical observations to support his view.

Three Cases of Motor Aphasia from Injury to the Head, Two of Which Were Rapidly Cured by Operation.—David Newman says that in the first case the injury, without producing a fracture of the skull, induced complete unconsciousness, followed by epileptiform fits, and while unconsciousness was returning complete paralysis of the right arm and leg appeared. The operation was performed on the tenth day after the accident, and the patient had completely recovered from all the symptoms of injury on the twentieth day. In the second case the injury had produced a depressed fracture of the skull associated with complete unconsciousness, and on the fourth day epileptiform attacks developed, involving primarily the right arm and leg. On the fifth day the skull was trephined, the bone was elevated and blood was removed, and on the twenty-eighth day the patient had completely recovered. In the third case the injury produced aphasia and unconsciousness only, there were no fits or paralysis, an operation was not performed, and the patient made a slow recovery during four months.

British Medical Journal, July 26, 1902.

Antistreptococcus Serum in Puerperal Fever.—Walter E. Fry has treated a case of puerperal fever in a primipara by the injection, once daily for three successive days, of 10 c.c. of antistreptococcus serum. Uterine douches and other methods of treatment were persevered with throughout, but the patient succumbed on the day following the last injection.

A Case of Movable Liver, with Greatly Distended Gall-Bladder, Relieved by Cholecystotomy.—David Newman has observed a case of this kind which is of interest because of the rarity of the condition as well as on account of the fact that the diagnosis was obscured by a greatly distended gall-bladder. The fluid filling this organ contained a large number of minute gallstones, but no impacted calculi were found in the dilated biliary ducts. The patient made an excellent recovery.

A Fertile Family.—Alex. J. Wilson records his experience with a primipara, thirty-one years of age, who, six months and a half after her marriage, gave birth to triplets, all being born alive, but dying twelve hours after birth. Thirteen months later twins were born, who were also premature (seven months). One of the twins died of bronchopneumonia when it was three months old, the other is still living and in good health. Thus, there were five children born in a little over one year and a half from the date of marriage. This unusual fertility is apparently on the husband's side, because his mother had twins twice, and the wives of five uncles—brothers of his father—all gave birth to twins.

Deutsche medicinische Wochenschrift, July 10, 1902.

Malaria and Carcinoma.—J. Goldschmidt cites the statistics of the island of Madeira in opposition to Loeffler's views concerning the antagonism of malaria and carcinoma. In Madeira malaria is practically unknown, yet the figures show that carcinoma here is also a rare disease. Surely if malaria and carcinoma are as antagonistic as Loeffler thinks, it is reasonable to suppose that the inhabitants of this island should show a fair proportion of cases of the latter disease.

Blackwater Fever.—Reinhold Ruge reports a case which shows that a small dose of quinine (.3 grams) may give rise to a severe attack of hæmoglobinuria, and, furthermore, that the so-called quinine prophylaxis is not in all cases to be relied upon as a preventive of blackwater fever. During the attack quinine enemas, as recommended by Kleine, are usually well borne by the patient, and seem to be of value in the treatment of the general condition. Microscopical examination of the blood can be relied upon for the prediction of an attack of blackwater fever, since twenty-four hours previous to the appearance of the clinical symptoms polychromatophilic degeneration may be observed, together with numerous macrocytes, microcytes, and "blood shadows."

Blackwater Fever and Malaria.—C. W. Schlayer reports a case of malaria complicated by blackwater fever in which the hæmaturia was apparently due to phenacetin, no quinine having been taken for ten days previous. The patient had just returned to Germany from Africa, in which country he had been free from malaria due to an efficient quinine prophylaxis. The diagnosis was at first in doubt, since a complicating pleurisy was present. Phenacetin (0.75 gram) was given; this was followed within twenty-four hours by a typical attack of blackwater fever. During this attack quinine (0.5 gram) was administered every three hours and much benefit obtained therefrom. The case is of interest in that it adds another to those few instances of phenacetin-hæmoglobinuria which have hitherto been observed.

Berliner klinische Wochenschrift, July 14, 1902.

Uterine Carcinoma Treated by Cancroin.—Schultz-Schultzenstein's patient was fifty-six years of age and had suffered from the carcinoma for over four years. For four months, except during short intervals, frequent inoculations of cancroin were administered. The total amount used was 10 c.c. Absolutely no improvement was obtained from the use of the cancroin, and laparotomy was subsequently performed with satisfactory result.

Treatment of Carcinoma by Cancroin.—Poten reports two cases of inoperable carcinoma, one of the uterus and the other of the breast, which were treated by cancroin, according to Adamkiewicz, without result, death occurring in both cases. The uterine case received during twenty-four days a total of sixteen injections or 13.5 c.c. of cancroin. The mammary case received eighteen injections, or 20 grains of cancroin, in forty-seven days. In both cases the diagnosis had been established by microscopical examination.

Cancroin in the Treatment of Carcinoma.—N. Nothnagel says that the cases recently reported by Adamkiewicz as carcinoma of the stomach, and in which a cure is claimed to have been produced by inoculation of cancroins, cannot with any degree of certainty be regarded as carcinoma. The case came under the personal observation of Nothnagel. The patient was in poor general condition, very anæmic, and complained of vomiting after eating. There was no pain in the epigastric region, but slight susceptibility upon pressure. Palpitation failed to show the presence of any tumor. The test breakfast showed neither hydrochloric or lactic acid. In face of these facts it is impossible to regard the case as one of carcinoma.

Treatment of Gout with Quinic Acid.—Huber and Lichtenstein report the successful treatment of five cases of gout with sidonal, which is chemically an anhydride of quinic acid. In all the cases the daily dose employed was ten grams. In every instance the result obtained was very satisfactory, the local and general symptoms being quickly relieved. It was interesting to observe that the more acute the case the more marked was the relief obtained. Observations were made upon the excretion of uric acid in four of the cases. Without exception the excretion of this acid was lessened during the administration of the drug. The reason for this is not entirely clear, but it seems most probable that the presence of this drug in the system lessens the formation of the acid.

Münchener medicinische Wochenschrift, July 15, 1902.

Serum Diagnosis of Tuberculosis.—Franz v. Gebhardt and Arpad v. Torday have tested the blood serum of 176 persons for its agglutinating power against the bacillus tuberculosis. The persons examined included both tuberculous and non-tuberculous individuals. For the tests the homogeneous cultures of Arloing were exclusively used. 74.7 per cent. of the tuberculous cases gave a positive reaction, while the serum of 34.5 per cent. of the non-tuberculous also agglutinated the cultures. From these figures it is evident that the reaction is of comparatively little value in the diagnosis of tuberculosis.

Operative Treatment of Tuberculous Peritonitis and Renal Tuberculosis.—Weisswange reports four cases of tuberculous peritonitis which were cured by laparotomy and two cases of renal tuberculosis in which a like result was obtained by nephrectomy. Great interest attaches to the reason why in many instances these operations are followed by a gradual disappearance of the tuberculous process not only in the locations operated upon but often also in other regions of the body. It is probable that a partial explanation is to be found in the evacuation of large quantities of tubercle bacilli with their products during the operation, but it seems most likely that the chief cause is the large increase in leucocytes, which takes place in the blood during the operative procedures. It may now be regarded as established that the bactericidal substances present in the blood are of leucocytotic origin. It is therefore certain that the leucocytosis produced by the incision is a prime factor in the disappearance of the tuberculous process.

French and Italian Journals.

The Pathogenesis of Psoriasis.—Guiseppe Verrotti holds that psoriasis depends upon an acid autointoxication, and in proof of his opinion adduces the results of urological researches. The skin, during the process, constitutes a means of elimination, which, according to the necessities of the case, either helps out the renal function or takes its place entirely. The activity of the process depends upon the degree of acidity and the renal sufficiency, being in direct ratio with the former and in inverse relation with the latter. This view of the pathogenesis of psoriasis explains many clinical facts which are in themselves apparently contradictory, such as cases of psoriasis accompanied by general systemic changes, as well as the numerous cases which are accompanied by such a state of relative well-being as to justify Kaposi's remark that psoriasis is a disease of the vigorous.—*Giornale Internazionale delle Scienze Mediche*, June 30, 1902.

Some Unusual Facts Discovered During the Examination of Malarial Blood.—G. B. Mariotti-Bianchi, during the anti-malarial campaign at Grossetano, observed four cases in which an examination of blood taken from the finger showed a deviation from the normal. The annular form of parasite was found as usual, with a few semilunar ones, but in addition there were adult forms in the circuating blood. The author also had the good fortune to catch a sight of a corpuscle at the very moment when it was breaking open to give egress to the semilunar bodies. Bignami and Bastianelli, as well as other writers, state that these bodies do not appear before the seventh and eighth, rarely the fifth or sixth day of the disease, and the author agrees that this is the rule. In one of the cases which he reports, however, he found them at the first examination, made at the end of the first febrile attack. The patient had never suffered from malaria before.—*La Riforma Medica*, July 12, 1902.

A Grave Case of Traumatic Tetanus Cured by the Tizzoni Antitoxin.—Eustachio Miraglia reports the case of a youth of sixteen years suffering from tetanus in aggravated form. The contraction of the jaw was so great that no amount of force could overcome it, and the muscles of trunk and limbs were in a condition of almost complete rigidity and the seat of atrocious pain. A subcutaneous injection of Tizzoni's antitoxin was given, 5 grams at a dose, in view of the gravity of the case. The next day the improvement in the patient surpassed all expectations. The contracture of all the muscles was greatly diminished, the arms could be moved and the mouth opened sufficiently for the administration of solid food, which could be masticated and swallowed with ease. Two grams were given that day, and a gram on each of the three days following. Recovery was complete.—*Giornale Medico del Regio Esercito*, June 30, 1902.

The Pupillary Reaction to Light in New-born Cats.—Tribondeau quotes Max Schultze as authority for the statement that the cat is born with closed eyelids on account of incomplete development of the retina. Nevertheless, after incising the lids at the point where they open later, and quickly carrying the animal into sunlight with the eyelids open, a contraction of the iris is produced. This reaction is equal on the two sides. The phenomenon is manifested directly after birth, but becomes more marked in the following days. The ordinary drugs have their effect on the iris in the first days, atropine has its usual dilating effect, but eserine exercises at that time a dilating effect opposite to the way in which it acts on the pupils of an adult. Further histological researches will show the anatomical condition of the retina at this period of the cat's life, but these experiments already show that from birth this membrane can be the starting point of light reflexes of the iris.—*Journal de Médecine de Bordeaux*, July 6, 1902.

Bathing the Nasal Fossæ.—Dereq declares that this operation is a simple proceeding, and gives the following directions: An absolutely clean drinking glass is used. It is washed out at the last moment with boiled water, and filled with a lukewarm solution of boric acid or whatever other solution is indicated in the special case under treatment. A basin is placed in front of the patient. With one hand the glass is held in place, keeping up a light pressure at the base of the nose. The head is held in the vertical position and respiration is uninterrupted through the open mouth. The bottom of the glass is slightly raised, and gradually, to the point of immersion of the tip of the nose. If the penetration of the nose by the liquid does not take place the head should be inclined backward very slightly for a few seconds. In this way the liquid will reach the posterior orifice of the nasal fossæ. The glass may then be put down and the liquid expelled into the basin. The length of time that this process should be continued and the amount of liquid used will depend upon the extent of the trouble to be treated. Between the treatments, the patient may gently blow the nose to express the accumulated mucus, or the foreign bodies which the bathing has rendered movable.—*Journal de Médecine de Paris*, July 6, 1902.

Melanosarcoma of the Thumb.—Brin and Papin report this rather unusual case. The patient was a woman o fifty-two years. The tumor developed in the first phalanx of the thumb. It began as a small movable nodule, which grew little by little. It was first noticed about a year before it was brought to the attention of the writers. For three months the patient had been using ointments on it, but they only inflamed the skin and produced ulceration. The tumor had developed on the inside of the thumb. It had grown in the direction of the tendons and was now hardly movable. The ulcerated skin over the central part of the tumor, especially at its periphery, was dark in color, characteristic of the growth. There were no enlarged ganglions. The thumb and metacarpal bone were extirpated. Examination showed the tumor to be melanotic with fusiform cells. At certain points the cells had invaded the papillæ of the derma, and at other points the sarcomatous tissue remained separated by a thick layer of connective tissue. The grains of melanin were recognizable by their histo-chemical characteristics. They were both intra- and extra-cellular, and were clumped together in considerable masses. Melanosarcoma is not often seen on the hand or foot.—*Bulletins et Memoires de la Société Anatomique de Paris*, February, 1902.

Revue de Médecine, July 10, 1902.

Potato Treatment in Diabetes Mellitus.—A. Mossé states that the administration of potatoes as a substitute for bread in diabetes mellitus and surgical diabetes has been found to be not only non-injurious, but useful. It cannot be called a form of treatment of the disease itself, but it constitutes an indirect method of lessening the glycogen and of exciting the glycolytic functions of the organism. The symptoms dependent upon hyperglycogenesis are in consequence attenuated. The author reports cases, and gives directions for the administration of potatoes, as to quantity and mode of preparation.

Aneurysm of the Ascending Aorta.—Prof. D'Espine concludes from his researches that there is a special form of aortic aneurysm characterized by an anterior diverticular pocket, which has important relations with the pulmonary artery or the conus arteriosus. The pathognomonic symptoms are a pulsation to the left of the sternum, and a special sphygmographic tracing differing from that of fusiform aneurysm. The possible complications are constriction of the pulmonary artery by pressure, pulmonary insufficiency from valvular union, or artero-venous aneurysm from perforation of the pulmonary artery. The systemic results are those of venous stasis.

On the Mechanism of Intestinal Infection in Dysentery.—L. E. Bertrand says that the fact that the intestines are under certain conditions a closed vessel, as it were, is as favorable to the production of dysentery as Dieulafoy has shown it to be of appendicitis. In constipation the condition exists and causes rectitis, which, according to Virchow, is the chief etiologic factor in dysentery. It exists also at the beginning of dysentery when the dejecta are composed exclusively of mucus, blood, and pus; the intestinal depletion produced by the first purgation causing scybalæ. The administration of large doses of opium, absorbents, and astringents in the beginning or during the course of dysentery causes this condition, and is the worst possible form of medication, especially in hot climates. It cannot be repeated too often that the only rational and efficacious treatment in dysentery consists in evacuating medication. All else is merely accessory.

Revue de Chirurgie, July 10, 1902.

Coxa Vara of Adolescents.—Robert Piqué describes this deformity, which consists in a diminution of the angles of inclination and declension of the neck of the femur. It may be congenital or acquired, appearing in the latter case at adolescence. It comes on insidiously, without any preceding rachitis, and the femur in which it occurs is usually larger than the one of the opposite side. It acts therefore as a compensatory process. There are two stages in its development; the first a painful one, during which the deformity causes symptoms of osteoarthritis with contracture, causing a marked restriction of movement, and tending to keep the limb in a position of adduction and external rotation. The second stage is a stationary one, during which all irritative symptoms disappear, but the functional disorders persist. Treatment consists of rest in bed and extension. At a later stage a supracondylar osteotomy might, if necessary, be resorted to, for the correction of a too extensive deformity.

Treatment of Contusions of the Abdomen.—L. Cahier says that in cases when the patient is conscious and not in pain, 0.01 of morphine may be given hypodermically. He should be questioned at this time as to the details of the accident. If there are more or less violent abdominal pains, vomiting, etc., the same dose of morphine should be given, and special care be exercised that no drink of any kind be given to the patient. Patients in syncope or suffering from shock should be placed lying with the head low, and should be warmly covered. Injections of ether, caffeine, or spartein should be administered. The patient should be catheterized as soon as he is placed in bed, to ascertain whether the bladder has been wounded, again a few hours later to find out whether there is oliguria or anuria. The author does not believe that opium masks the symptoms, for paradoxical pulse, temperature, pain under pressure, muscular contraction, etc., will suffice for diagnosis, and will not be affected by the drug. Details for operative intervention are given.

Cerebral Hemorrhage Occurring During Chloroform Anæsthesia.—M. Boureau reports the case of a woman of fifty-two years upon whom an operation was performed for the removal of a frontal tumor. The patient took the chloroform easily; the operation lasted forty-seven minutes, anæsthesia an hour and five minutes, 28 c.c. of chloroform having been taken. During the operation nothing abnormal occurred. After the patient was placed in bed the nurse perceived that her pallor was extreme, respiration stertorous, pulse small, and skin cold. In spite of frictions, subcutaneous injections of artificial serum, ether, caffein, etc., this condition persisted for eight hours after the operation, when the patient regained consciousness. There was found to be complete paralysis of the left arm, beginning paralysis of the left leg, and slight paralysis of the right side of the face. The next day the leg was entirely paralyzed. Improvement was marked in a few days, and recovery will probably ensue in a few weeks. The cause of the occurrence is difficult to understand. Had the patient not recovered, her death would undoubtedly have been attributed to the chloroform anæsthesia.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Cellular Toxins, or the Chemical Factors on the Causation of Disease. By Victor C. Vaughan and Frederick G. Novy, M.D. Fourth edition. 8vo, 480 pages. Lea Brothers & Co., New York. Price, cloth, $3.00 net.

The Essentials of Histology, Descriptive and Practical. By E. A. Schafer, L.L.D. Sixth edition. 8vo, 416 pages. Illustrated. Lea Brothers & Co., New York.

Book Reviews.

Dynamic Aspects of Nutrition and Heredity. By Frank Harridge. New York: Wm. Wood & Co., 1902.

An explanatory title of the above might be, "An attempt to reduce the problems of physiology and physiological chemistry to a physical basis."

The nervous system regulates all the various processes connected with tissue change by virtue of the force generated and developed in its own metabolism. These changes constitute a continuous series of rhythmic movements, the influence of which is felt throughout the body. Nutrition, preventive medicine, curative medicine, and the laws of heredity are to be explained directly, at least, by alteration of these rhythmic movements.

A strangely interesting and odd conceit that has been suggested before, but which has never been worked out so well as by Mr. Harridge. Without agreeing at all with the writer's conclusions, the reviewer ventures the opinion that there are few books that fall into the hands of physicians that will be read with greater interest than this one. The concluding chapter on heredity is not up to the mark set by the first chapter on the active forces of living organisms. Although Mr. Harridge may not convince many, he is sure to interest some.

The Practitioner's Manual. A Condensed System of General Medical Diagnosis and Treatment by Charles Warrenne Allen, M.D., Consulting Genitourinary Surgeon to the City (Charity) Hospital; Consulting Dermatologist to the Randall's Island Hospital; to the Hackensack Hospital; to the Bayonne Hospital; to the Infant Asylum of the Holy Rosary. Professor of Dermatology at the New York Post-Graduate School, etc. Second edition, revised and enlarged. 889 pages. New York: William Wood and Company, 1902.

The fact that a second edition of this work has been required within three years of the original issue seems to prove that it has served its purpose satisfactorily. The diligence of the author in collecting so many formulæ and arranging them under their respective headings is worthy of praise. Among the new chapters we note those on Gastroptosis and Enteroptosis, Mediterranean Fever, Meralgia Paræsthetica, Mongolism, the Fourth Disease as described by Dukes, and Splenitis and Poliomyelitis in the Adult. A new chart and many new formulæ have been added, while other prescriptions of less importance have been dropped from the text. The differential points in diagnosis have been well brought out, so that the treatment can be more intelligently employed. The work is not intended as a textbook, but as a practical aid to the busy practitioner in search of help. Many of the minor ailments so often omitted in larger works are here incorporated, and will be welcome reading to the clinician.

A Reference Handbook of the Medical Sciences, Embracing the Entire Range of Scientific and Practical Medicine and Allied Science. By various writers. A New Edition Completely Revised and Rewritten. Edited by Albert H. Buck, M.D., New York City. Volume IV. Illustrated by chromolithographs and eight hundred and fifty-nine half-tone and wood engravings. New York: William Wood & Company, 1902.

One hundred and fourteen writers have prepared the many times greater number of articles contained in the eight hundred and seventy-three pages of this fourth volume of the Reference Handbook. The titles run in alphabetical order from "Ergot" to "Infiltrations," including such important subjects as Erysipelas, Evolution, Eye, Food and Food Poisons, Foot (including Clubfoot), Fractures, Gall-Bladder, Gangrene, Genital Organs, Gestation, Glaucoma, Goiter, Gonorrhœa, Gout, Gunshot Wounds, Hands and Fingers, Harelip, Headache, Heart, Heredity, Hernia, Hip-joint, Histological Technique, Hospital Ships, House Santitation, Hysterectomy, Hysteria, Immunity, Impregnation, and Infancy. It is an extremely difficult task for a reviewer to do any sort of justice to a work of this nature in the necessarily limited space of a book notice. Many of the articles above mentioned are practically monographs and deserve independent reviews, while scores of other articles, perhaps no more than half a column in length, yet compact little treatises in themselves, must be passed by without even mention. Such, for example, are those dealing with the various articles of the materia medica, the health resorts and medicinal springs of Europe and America, minor diseases of the skin and other organs and tissues, anatomical structures, etc., etc. Many of these are perfect in their way, contributed by men whose absolute knowledge of their subject has enabled them to condense to the utmost without the sacrifice of lucidity. With this volume the encyclopedia is half completed, and any doubts that may have been entertained regarding the value of the finished work must be dispelled by the appearance of this, the latest and in many respects most important and best of the volumes of the series.

Einführung in die Farbstoffchemie für Histologen, von Dr. L. Michaelis, Assistenzartz am Städtischen Krankenhause Gitschinerstrasse in Berlin. Berlin: S. Karger, 1902.

This book is divided into two sections, the first of which treats of the general chemistry of the staining agents considered. This section is both theoretical and practical in nature. Especial mention is to be made of the abundant use of graphic formulæ. These are always desirable in any work which deals with highly complicated and closely-related chemical compounds, and their abundant use adds greatly to the value of the work, particularly for those who are not accurately familiar with the pure chemistry of the substances considered. In the second section the various staining methods as used by histologists are individually considered. The chief value of this portion of the work lies in the fact that the author considers principles rather than processes, thus encouraging the reader to independent thought and an endeavor to attempt original work along the lines indicated. For the reasons above indicated it is the most valuable work which has yet appeared upon this topic.

Fragments in Philosophy and Science, being Collected Essays and Addresses by James Mark Baldwin, P.D., etc., Stuart Professor in Princeton University. New York: Charles Scribner's Sons, 1902.

No extensive review is needed of this book of essays and addresses which have been published in various philosophical reviews and scientific journals during the past ten or fifteen years. To those medical men who are accustomed to delve a bit into writings on philosophy and psychology this volume, embodying the best thought of an advanced thinker, will be welcome; others will do no more than read the titles of the chapters. Of special interest to physicians are the chapters on Physilogical Psychology, of which "it is useless as yet to expect, and profitless to attempt, more than minor generalization." Although "activity of research and proportionate fruitfulness of result are preparing the way, we believe, for greater discoveries." The chapter on the origin of volition in childhood, in which it is contended that "the child's first exhibition of volition is its repeated effort to imitate movements seen, noises heard, etc." The three elements of the volitional process are desire, deliberation, and effort, desire taking its rise in visual suggestion and developing under its lead. The chapter on the Origin of Emotional Expression is perhaps the best example the book contains of the author's argumentative and critical faculties. In spite of its mildly sarcastic vein, it is pleasantly written.

Zum Studium der Merhfähigkeit Experimental-Psychologische Untersuchung. Von Dr. Aug. Diehl, Nervenarzt in Lübeck. Mit einem Vorwort von Prof. Dr. Aug. Forel. Berlin: Verlag von S. Karger, 1902.

Diehl describes the series of careful and varied experiments he has made on eight persons—children and adults—to determine their capacity for retaining, under normal conditions, optic impressions of a simple kind. The tests included numbers, the relative position of a certain object on a white background, and colors. The results show how untrustworthy the memory is even a short time after the impression has been received.

Ueber die Behandlung der acuten Nierentzündungen und der Schrumpfniere. Von Prof. Dr. Carl von Noorden, Oberarzt des Städtischen Krankenhauses in Frankfurt a. M. Berlin: August Hirschwald, 1902.

The first of the five chapters of this interesting and instructive brochure, by a well-known authority, is devoted to a review of the customary treatment of acute and subchronic (parenchymatous) nephritis, and of contracted kidney. It is followed by a consideration of the metabolic changes in their bearing on the dietetic treatment. In the last two chapters the dietetic and physical therapy of the above-mentioned affections are set forth in accordance with the author's views, which differ in not a few respects from those given in the textbooks.

Der Sauerstoffmangel als Bedingung der Erkrankung und des Ablebens des Organismus. Von Prof. Dr. C. Pavlinoff. Berlin: August Hirschwald, 1902.

Pavlinoff undertakes to show that lack of oxygen is the condition essential to function and consequently also to life, and the evolution of the organism—in other words, that all functions of the higher animals depend upon oxygen hunger. He considers that the struggle for oxygen between the cell and the irritative agent constitutes the process of inflammation, and that the increase of cells that attends inflammation is the result of diminished acute oxygen hunger. Lack of oxygen in cell life he regards as a factor without which it would be difficult to explain life, evolution, involution, inflammation, and other pathological and physiological processes.

The Life of St. Luke. By Edward Clapton, M.D., F.R.C.P. Late Physician to St. Thomas's Hospital London: J. and A. Churchill, 7 Great Marlborough Street, 1902.

The title of this little volume indicates its contents, as the writer merely gives a simple narration of the life of this apostle. He speaks of him as "a young Greek physician from Antioch, with excellent credentials, who had not only received a regular medical education, but was also a Jewish proselyte." After following his life through the Gospel of St. Luke, he continues with it as it is presented in "The Acts of the Apostles," for there is "no break in the continuity of his narrative." The writer discusses the question as to whether Luke and Antipas were one and the same person, and closes with a description of St. Luke's burial place.

Nothnagel's Encyclopedia of Practical Medicine. Diphtheria, by William P. Northrup, M.D. Measles, Scarlatina, and German Measles, by Theodor von Jürgensen, M.D. Under Editorial Supervision of Alfred Stengel, M.D. W. B. Saunders & Co., 1902.

Commencing with a history of Diphtheria, the author next describes the etiology and the pathology of the disease. Following this is an abundance of interesting statistics covering pages 140 and 150. The symptomatology so important in this disease deserves especial comment. The modern views concerning (*a*) fibrinous diphtheria; (*b*) mixed phlegmonous or strepto-diphtheria; (*c*) septic or gangrenous diphtheria (septicæmia) should be read to be appreciated. The articles on Fever, on the Pulse, Bradycardia, and Tachycardia are noteworthy. Nasal diphtheria, laryngeal diphtheria, and the tracheal, bronchial, and conjunctival types are important. The urine, the heart, and the effects of the toxin on the nervous system are exhaustively discussed. The complications and sequelæ of diphtheria are well described. The treatment is divided into general (antitoxin) and operative (*a*, intubation; *b*, tracheotomy).

Articles on Intubation and Tracheotomy, amply illustrated, form a large part of this chapter on treatment. Why the author finds it necessary to condemn rectal feeding, as for example, on page 132, "Rectal feeding is to be regarded as a last resort," it is difficult to understand. Rectal feeding has been the means of saving many a life after intubation and can be recommended especially in nasal diphtheria. It stands to reason that pushing a rubber catheter in nasal gavage does not benefit the diphtheria, nor the patient. When vomiting persists after mouth or nasal feeding, rectal feeding should be given proper consideration.

We regret to note the absence of Prof. Baginsky's article on Diphtheria which appears in Nothnagel's original series.

The articles on Measles, Scarlatina, and German Measles are translations of that well-known authority, Prof. Jürgensen. Modern scientific research has so changed our views concerning methods of diagnosis that the comparison with older works reveals many changes.

In the treatment of measles, one point, page 361, strikes us as very important, namely, "Have plenty of fresh air in the room and don't darken the window." Light is imperative. Do not let the light strike the eyes directly, but have the child's back to the light. Such modern therapeutic measures tend to disseminate proper views which conform to modern tendencies. The article on Scarlatina and German Measles is a translation, and has been edited with American additions, many new points having been added.

Bibliographia Lactaria. Deuxiéme Supplément (Année 1901) a La Bibliographie Générale des Travaux Parus Sur Le Lait Et Sur L'allaitement Jesqu'en 1899, par Le Dr. Henri De Rothschild, Lauréat de la Faculté de Médecine. Paris, Octave Doin, Editeur, 1902.

This excellent work is needed for those interested in infant feeding and the dairy. It is divided into two parts: Part 1 deals with human milk; gives all literature on physiology, pathology, hygiene and frauds, dietetic and therapeutic measures, fermented milk, skim milk, sterilized and condensed milk, transmission of disease through milk.

Part 2 gives all literature to date on feeding—natural and artificial methods—modification of milk, and bottle feeding. To those desiring complete data concerning all American and foreign literature, we would recommend the perusal of this work. To the writer and teacher it is valuable in bringing home current topics pertaining to milk in every phase. Valuable time is lost in hunting through literature, and frequently excellent papers are overlooked. The profession will certainly appreciate such reference hand-books.

Intubation du Larynx. Instruments Technique. Avantages. Par Le Dr. Perez Avendaño, ancien interne des hopitaux de Buenos-Aires. Membre correspondant de la Société de Pédiatrie de Paris. Préface du Dr. Marfan, Professeur agrégé à la Faculté de médecine. Médecin de l'hôptial des Enfants malades. Paris: C. Naud, 1902.

The writer treats this subject quite extensively. The book is divided into two parts. The first part is essentially historical and critical, and is illustrated by plates, it is devoted to a study of intubation instruments. There is a special chapter in which the author calls attention to the advantages of the modifications of the instruments which he himself suggests. The second part is devoted to the technique of intubation. Indications for the operation are discussed as well as its difficulties and possible complications. Finally, the two operations of intubation and tracheotomy are compared. Statistical tables and a bibliography are appended.

The Practical Medicine Series of Year Books. Vol. VI. General Medicine. Edited by Frank Billings, M.S., M.D., Head of Medical Department and Dean of the Faculty of Rush Medical College, Chicago. With the Collaboration of S. C. Stanton, M.D. Chicago: The Year Book Publishers.

The volume before us is the second dealing with General Medicine. Special attention has been paid to Typhoid Fever, Malaria, Yellow Fever, Dysentery, diseases of the Liver and Pancreas and Gastro-intestinal disorders. In all of these articles we find a concise and satisfactory exposition of the most recent knowledge of the subjects treated. For those who have limited time for reading, this synopsis can be cordially recommended.

Water Supply, Considered Principally from a Sanitary Standpoint. By William P. Mason. Third edition. New York: John Wiley & Sons, 1902.

So much material has lately been added to our general knowledge upon the subject of water supplies, that this, the latest edition, of Professor Mason's book has been largely rewritten. It contains an admirable discussion of water supplies, their sources, relation to disease, and methods of purification. In the present volume the chemical and bacteriological examination of water is not considered. This is to be regretted, as it renders the treatment of the general subject of water incomplete, and deprives the book of much of the practical value possessed by previous editions.

Minor Surgery and Bandaging; Including the Treatment of Fractures and Dislocations, the Ligation of Arteries, Amputations, Excisions and Resections, Intestinal Anastomosis, Operations upon Nerves and Tendons, Tracheotomy, Intubation of the Larynx, etc. By Henry R. Wharton, M.D., Professor of Clinical Surgery in the Woman's Medical College of Pennsylvania, Surgeon to the Presbyterian Hospital, etc. Fifth edition. Revised with 500 illustrations. Philadelphia and New York: Lea Brothers & Co., 1902.

Wharton's Surgery has long been a popular text-book with the student of medicine, and new editions have been found necessary from time to time, in order to keep the work abreast of modern requirements. Minor surgery and bandaging are what the student is actually first brought in contact with in a practical way, and it is essential that he should have the assistance of a text-book which is compact, concise, and comprehensive. This volume has been found by experience to fill satisfactorily these requirements, and it has in consequence become a standard. The present edition is amplified to some extent over its predecessors and several new illustrations have been introduced. As the title page indicates, the volume contains much that does not come properly under the head of minor surgery, but which might be more accurately described as emergency surgery, and does not in consequence belong in a book devoted to real minor surgery. However, emergency surgery must often be done when the facilities for minor surgery only are at hand, and the value of the book is enhanced by being thus made more comprehensive. In size and appearance this last edition is not different from the others, and the illustrations, as a rule, serve their purpose very well.

Therapeutic Hints.

Nux Vomica used specifically becomes an invariable remedy. Five drops of nux in half a glass of water, a teaspoonful every half hour. In atonic, gastric, and intestinal troubles, tongue coated, pasty, yellow, pale; pale mucous membranes, nausea, vomiting; acute pain in the small intestines; acute pain in the umbilicus, with pale circles around the mouth; general inactivity, indisposition, and feebleness. These are the indications for this remedy.

—*Toledo Medical and Surgical Reporter.*

Hot Water in Scarlatinal Nephritis.—Hot water irrigation of the bowels should be employed whenever the quantity of urine is diminished or when convulsions occur. In a child aged three years, 500–750 c.c. water at a temperature of 43° C. should be introduced by means of a rectal tube passed into the rectum for a distance of 2½ c.m. If the water is returned at once the process is repeated and irrigation should be performed every six or eight hours. After three or four administrations the kidney begins to act, and abundant diuresis takes place.

KERLEY.

Cramps of Legs.—Cramps of legs are influenced by the valveless condition of the inferior vena cava, and consequent hydraulic pressure, by constipation and its consequent pressure on the iliac veins, and to gouty diathesis, leading to the deposit of urates in the muscles surrounding the congested veins in the legs, therefore, in the remedial treatment of cramps, attention should be directed mainly toward (1) the relief of constipation, (2) the removal of uric acid toxin, (3) the establishment of better circulation. An effective chologogue is of first importance, and that, combined with a uric-acid solvent, the circulation of the blood may be quickened and its subalkalinity may be neutralized, and the toxins removed. A more active interchange having thus been established between blood and tissues, the third condition is fulfilled.

—JOHN McDONALD in the *Northwestern Lancet.*

Capillary Stasis.—The more experience a physician has in the treatment of children, the more fully he becomes convinced that belladonna is essential to his success. The dose must be small, as children are very susceptible to the influence of this drug. In summer diseases of children cases are frequently seen showing marked dullness of the eyes, dilated pupils, with an almost resistless desire to sleep. Belladonna is a specific for this condition, and no other remedy can fill its place.

Nitric Acid.—The indications for nitric acid are exceedingly plain, and sometimes a long train of symptoms will disappear when this agent is given according to its symptomatology. The tongue and mucous membranes are of a violet color and sometimes carmine or clear red. The membrane is apparently transparent, though its color is plainly seen. The membranes are dry from a deficiency of the secretion. There is general inactivity of the intestinal glands and unusual lack of tone, with a tendency to diarrhœa.

White Wood as a Cure for the Tobacco Habit.—The liriodendron tulipifera, also known under the names of white poplar and white wood, is one of the largest lumber-producing trees native to this country. The outer bark constitutes a very efficient cure for the tobacco habit. The fresh inner bark may be chewed or the powdered bark may be mixed with sugar and extract of licorice and compressed into a tablet containing five grains of the bark. A tablet is to be allowed to dissolve in the mouth whenever a desire is experienced to smoke or chew.

Neurasthenia.—A. D. Rockwell says that in his own experience electricity has proven the best remedy. There is, however, a most marked variation in the susceptibility of patients to this therapeutic measure. There are cases in which more than ten to fifteen milliamperes on any part of the body produce irritability, while one-half this strength applied to the head becomes decidedly disturbing. On the other hand, there are neurotics whose very condition seems to enable them to endure an unusual strength of current, which it is found necessary to decrease as soon as improvement is evident. Static electricity is especially valuable in conditions of disturbed circulation resulting in local congestion. He highly extols the action of static electricity in these conditions. In connection with prolonged application of high-tension currents over the kidneys he has observed in several instances the disappearance from the urine of albumin and casts.—*International Medical Magazine.*

Cholelithiasis.—The medical treatment is so often successful that surgical measures should never be resorted to until the case has been proven very chronic in character, unrelieved by treatment, or when the stone is very large and suppurative conditions arise. Morphine is necessary to control the attack at the beginning, and is the best antispasmodic to use. Heat locally or mild counter irritation might aid. Some recurrent cases respond to internal treatment and should be given that chance. The ends aimed at are to increase and liquify the bile, perhaps render aseptic and possibly exert an alterative effect upon the mucosa. The diet has probably little effect, but the avoidance of fatty and rich foods and alcoholic liquors is recommended. Free use of water has a marked effect in stimulating increased flows of bile and might be combined with a little sodium bicarbonate or phosphate. The sodium salts seem to have a decided effect in aiding hepatic functions. Small doses of pilocarpin twice daily have a marked effect upon jaundice due to catarrhal inflammation.

J. B. McGEE.

Surgical Suggestions.

Surgical Treatment of Obstruction of Common Bile-Duct by Concretions.—In cases of cholelithiasis the common duct has to be attacked in one out of five or six cases. Choledochotomy is preferable to all other methods. Crushing the stone is applicable only to soft stones and then fragments are apt to be left. Cholecystenterostomy should never be performed for stone, as it leaves the cause untouched, and stones are apt to form again following closure of the small opening, which is liable to take place. If the patient is too ill for choledochotomy, an anastomosis between the colon and gall-bladder should be done.—MAYO ROBSON in the *Lancet.*

Surgical Aspect of Carcinoma Uteri Complicating Pregnancy.—All partial operations are contraindicated as they usually fail, are harmful to the fœtus and of little benefit to the mother. If the growth can be completely removed, hysterectomy is recommended. If it is not possible to remove the whole of the tumor, then the pregnancy should be continued in the interest of the child. During the first six months vaginal hysterectomy is recommended, after that the abdominal operation is indicated. At times the cæsarian section may be done, but owing to the danger of septicæmia, Porro's operation is preferable.—CHAS. G. CUMSTON in the *Boston Medical and Surgical Journal.*

No Ice-Cream Soda in Berlin.—The municipal authorities of Berlin, with a fatherly solicitude for the stomachs of the burghers entrusted to their guidance, have issued a decree that no iced drinks shall be sold in any place of public refreshment in that city. The limit of frigidity allowed is 10°C. or 50°F.

Society Reports.

AMERICAN ORTHOPEDIC ASSOCIATION.

Sixteenth Annual Meeting, Held in Philadelphia June 5, 6, and 7, 1902.

H. AUGUSTUS WILSON, M.D., OF PHILADELPHIA, PRESIDENT.

FIRST DAY.—THURSDAY, JUNE 5.

President's Address.—Dr. H. AUGUSTUS WILSON of Philadelphia delivered this address. He called attention to the steady increase in the number of applicants for membership, and to the more general recognition of orthopedic surgery in teaching institutions.

General Management and Constitutional Treatment of Tuberculosis of Bones and Joints, with Special Reference to the Use of Tents.—Dr. H. P. H. GALLOWAY of Toronto, Ont., read this paper. He pointed out that, almost without exception, the textbooks on orthopedic surgery practically ignore the general management of tuberculous joint disease, and leave the reader to draw the erroneous inference that the mechanical treatment is the whole treatment. In the treatment of bone and joint tuberculosis drugs occupied a small place, though cod-liver oil, or preferably sweet cream, was often beneficial in winter. The diet should be nutritious and the food supply should be carefully adapted to the individual's powers of digestion. The more nearly the patient could be made to lead an out-door life without its inconveniences, the better. Relapses of tuberculous disease were apt to occur toward the close of the winter, and were often dependent upon enforced living in close and crowded apartments or hospital wards. The plan of treating such cases in tents at the Toronto General Hospital had been employed during the past year, and the results attained were such as to lead the surgeons and physicians there to enthusiastically indorse it. A distinctly favorable change was often noticed in one or two days, and the records of the hospital showed that the patients consumed a larger quantity of food, and ate it with greater relish. Improvement in the local conditions was quite as satisfactory, though slower in manifesting itself. Fresh air and sunlight should not, however, be used instead of, but as supplemental to the mechanical treatment, of bone and joint tuberculosis.

The Malignancy of Bone Tuberculosis.—Drs. JOEL E. GOLDTHWAIT and C. F. PAINTER of Boston presented a paper on this subject, which was read by Dr. Painter. The authors said that it was known that the extension of the disease, both in the lungs and in bone, was prevented by Nature's throwing out a wall of connective tissue. The subject was presented at this time to emphasize the fact that bone tuberculosis was by no means cured by the prolonged use of apparatus alone. A tabulated statement of the cases studied was presented, and it was shown that, in the majority of cases of recurrence, there was a local manifestation in the old seat of disease. Of the forty-seven cases in the table, twenty-nine were males and eighteen females, showing apparently the effect of the greater liability of males to trauma. Thirty of the cases had worn apparatus for varying lengths of time, and had been under reasonably careful treatment. The average age at which the exacerbation occurred was twenty-eight, and the average quiescent period was twelve and a half years.

Dr. JAMES K. YOUNG of Philadelphia remarked that in his textbook on orthopedic surgery were to be found several references to this important subject of out-door and constitutional treatment of tuberculosis.

Dr. B. E. MCKENSIE of Toronto, Ont., said that his experience with tuberculous persons living in tents had led him to place less and less confidence in the mechanical treatment of tuberculous affections as carried out in the use of braces. While as desirous as any one a few years ago to apply a brace or jacket to a person with Pott's disease, he was now reluctant to do so. The increased quantity of food taken and assimilated by persons leading an out-door life served to increase their resisting power.

Dr. N. M. SHAFFER of New York said that the paper on tent treatment recalled an experience that he had had in 1883 in the treatment of a patient in a city back yard. This experience had been so favorable that he had many times since then adopted this plan.

Dr. John RIOLON of Chicago thought Dr. Painter had made a mistake in assuming that the operative removal of tuberculous foci never resulted in relapses such as occur after mechanical treatment.

Dr. ROBERT W. LOVETT of Boston said that by a series of measurements he had found that during the active progress of the disease the weight and height of the children were distinctly below the average of other children attending the clinic, and that even in the very earliest stages of joint tuberculosis they were distinctly below the average of healthy children in the same class, both as to height and weight. He considered rest during the acute stage of great importance, and hence advised that these children should remain recumbent from two to four hours each day, besides getting their full share of rest at night.

Dr. HARRY M. SHERMAN of San Francisco said that he had found that when he sent children suffering from joint tuberculosis to the country they improved even though the mechanical treatment received so little attention that they returned with their braces nearly dropping off of them. He was surprised at the frequency of local as compared with visceral recurrences in the statistics presented in Dr. Painter's paper, but this study gave him renewed courage, for if local recrudescences were going to take place so frequently he should feel that he had not been very wrong in the years when he had resorted so freely to early incision. Certainly early operation gave opportunities for life which would not otherwise be presented.

Dr. HENRY LING TAYLOR of New York said that for the past two summers he had had an opportunity of watching the effect of sending crippled children to the seashore, where they lived, for the most part, in tents. Despite the absence of proper supervision of their braces, these children had shown a striking improvement in their abscesses as well as in the general health.

Dr. FRANK E. PECKHAM of Providence said that he had had occasion to send children both to the seashore and inland, and it seemed to him that those sent to the seashore did far better.

Dr. GEORGE G. DAVIS of Philadelphia said that undoubtedly in certain instances tuberculosis was at first a local disease, and where it involved the bones or joints was capable of eradication by early operation.

Dr. PAINTER, in closing the discussion, said that he had been misunderstood in the matter of operative interference. As a matter of fact, the table presented contained a number of operative cases that relapsed. He believed that the time was coming when operative interference would be of a different character from what it had been in the past when described as "early interference."

Two Cases of Elevated Scapulæ.—Dr. A. J. STEELE of St. Louis reported these cases with photographs, because, he said, Jonathan Hutchinson had recently declared that such cases are very rare in England. The lower angle of the scapula was carried inward and overrode the spine, pointing almost to the middle of the opposite scapula. He was inclined to think the condition was congenital, although there was a history of traumatism. In the second case the scapula was held in its unnatural position by ligamentous union. A number of these cases had been reported in this country.

Dr. N. M. SHAFFER said that he had seen such a case in 1886, and it had been published shortly afterward by the late Dr. H. B. Sands.

Dr. A. H. FREIBERG of Cincinnati said that there were really three classes of cases. In the first class there was associated considerable deformity, in the second there was simply an elevation of the scapula with a perfectly normal thorax and spine, and in the third class there was union between the scapula and the spine or between the scapula and the cervical rib.

Dr. H. L. Taylor remarked that two or three such cases were seen annually in a large clinic like that of the Hospital for Ruptured and Crippled in New York.

Dr. H. Augustus Wilson said that his two cases were apparently unique in that there seemed to be prolongations of the seventh cervical vertebra with distinct articulation, in one case, with the scapula.

Dr. Painter said that he had reported two cases last year.

Report of a Case of Congenital Deficiency of the Clavicles with Photogram and Radiogram.—Dr. Harry M. Sherman of San Francisco presented this report. The patient was a child of three years, markedly rachitic. There was no interference with the use of the arms, and the condition had been entirely overlooked by the family physician, who had referred the case because of the rachitis.

Dr. G. G. Davis remarked that as one of the chief functions of the clavicle was to aid in abduction, there must be some loss of function in such cases as the one reported.

An Apparatus for Paralysis of the Extensors of the Hands and Fingers.—Dr. G. G. Davis of Philadelphia exhibited this apparatus, which he had used in a case of severe crushing injury. In order to extend the thumb he devised the appliance exhibited. Two pieces of wire in the shape of the letter "V" were united at their angles and fastened to the thumb by adhesive plaster. By a rubber band attached to the dorsal side of this wire, and fastened by a cord to the wrist, extension was secured. The apparatus for the hand consisted of two lateral bars with a joint opposite the wrist-joint, and two springs, one on each side, which tended to keep it in an extended position. This was situated opposite the second joint of the fingers.

Remarks on Arthrodesis of the Ankle for Infantile Paralysis.—Dr. John Dane of Boston read this paper. He said that this form of paralysis usually comes on at about the age of eighteen months, and that the acute stage was usually passed before the age of two years. One year after the onset one should be able to tell what muscles were permanently injured. If operation were done early the foot would be found in a fairly good condition, and the bones and their articulations not deformed. When the foot was secured in a relatively normal position quite early the growth would go on in more normal lines. By avoiding mechanical support the unaffected and partially paralyzed muscles were not subjected to the injury inseparable to the use of constricting bands and straps. He made use of the simple internal incision, laying the joint thoroughly open. The objections usually made to the operation were the fear of not getting solid union and the danger of injury to the lower tibiofibular epiphysis with consequent shortening. To meet the first objection a skiagraph was presented, showing that true bony ankylosis was secured. The epiphysis would not be injured if the operation were carefully done. Again, an intentional irritation of the epiphys is often resulted in increased growth of the limb.

Dr. B. E. McKensie said that, from an experience with three cases in which he had operated for deformity of the foot caused by cessation of growth in the lower end of the tibia, it looked as if irritation produced there, either by disease, such as osteomyelitis or by fracture near the epiphysis, would result in harm. There should be sufficient room to make an incision of the joint without invading the cartilage itself, yet, he thought, the increased physiological action resulting from the process of healing might easily bring about an early synostosis, and hence there would be no further growth in the lower end of the tibia.

Dr. G. G. Davis said that one objection to arthrodesis was that it had to be done in young children in whom the bony tissue was very little developed, and the difficulty was to get bony union. He believed that in order to obtain bony union the joint must be immobilized for a very long period because of the softness of the tissues.

Dr. Dane, in closing, said that he thought the failures to secure bony union in young children might be due to an imperfect technique. The textbooks had made no plea for an accurate and thorough operation with an absolutely square mortising.

A Further Report of the Treatment of Neurotic Patients as They Are Seen in Orthopedic Practice.—Dr. B. E. McKensie of Toronto was the author of this paper. He pointed out that while organic disease might be present, the psychic element was often unduly prominent. One of the cases reported was one in which, after six years of needless invalidism, the patient had been vastly improved by a healthy but forceful discipline. The speaker expressed the fear that orthopedic surgeons too often kept up mechanical protection of a joint, to the detriment of their patients, for an unnecessarily long time. Discipline, always clearly cut and kind, must be maintained in these neurotic cases.

A Report of an Epidemic of Thirty-eight Cases of Infantile Paralysis.—Dr. Charles F. Painter of Boston reported this series of cases, which occurred between June and September at Gloucester, Mass., within a radius of four miles. The literature, he said, contained accounts of quite a number of such epidemics. The city of Gloucester had a population of about twenty-five thousand people, for the most part engaged in fishing. There had been only one death in this epidemic, and that had occurred in July. There were twenty-three males and nine females, and twenty-one of the patients were under the age of three years. Not one of the cases up to the present time had entirely recovered. He had investigated every likely source of infection in connection with this epidemic, looking into the sanitary condition of the dwellings, their location, the water, food and ice supply, but with negative result. The temperature chart seemed to show that more cases had developed in the excessively hot weather. The only important group of cases comprised about twelve, all occurring around the periphery of a cemetery.

Report of a Case of Double Pott's Disease, Cervicodorsal and Dorsolumbar.—Dr. R. Tunstall Taylor of Baltimore reported this case, which appeared, from a search through the literature, to be unique in that Pott's disease is supposed to be due to a tuberculosis affecting *adjacent* vertebræ. The patient was a child of seven years, in whom tuberculosis of the first, second and third lumbar vertebræ developed, and was subsequently followed by involvement of the fifth, sixth, and seventh dorsal vertebræ. The *x*-ray photograph plainly showed the two foci of disease.

An Additional Case of True Spondylitis Following Typhoid Fever.—Dr. Albert H. Freiberg of Cincinnati reported this case. The patient was an Italian boy of fifteen years, who had been admitted to hospital on February 1, 1901. He had been well up to a few days before, and the symptoms at the time were typical of typhoid. On March 9 the Widal reaction was negative. On March 20 he was allowed to sit up, and nine days later was permitted to be on his feet. He then complained of pain in his back. The pain was so great on April 7 that an anodyne was required. At this time he had been first seen by Dr. Freiberg. There was a decided projection, involving the eleventh and twelfth dorsal and the first two lumbar vertebræ. The muscles of the back were rigidly contracted. On April 11 he was placed in a plaster bed, and at once experienced marked, but not complete relief. On May 8 a plaster jacket was substituted, and on May 31, being entirely free from pain, he was discharged at his own request. In February of the present year

Dr. Freiberg saw this patient again, and found the deformity of the spine about the same and that there was still marked restriction of motion. The man had been working steadily at his trade and was the picture of health. The speaker expressed the opinion that these cases of typhoid spine could not be considered as due to a neurosis, but rather to a local process of an inflammatory nature.

Final Results after the Treatment of Pott's Disease.—Dr. Henry Ling Taylor of New York presented this communication. The histories were given and the tracings shown of thirty-eight cases of Pott's disease treated in private practice by the use of the Taylor spinal apparatus. Each case had been observed and the deformity measured at intervals for from ten to thirty-seven years. It was found that: (1) The disease was cured in thirty-two cases, the cure being practically perfect in a considerable number as regards health, figure and function; (2) The result was good as regards deformity in about half the cases, and that twelve showed arrest or decrease of the deformity; (3) Location was the most important factor as regards the progress of the deformity, the cervical region being the most favorable, the lumbar the next, and the dorsal the least; (4) It was necessary to continue spinal support in most cases long after the pathological cure, owing to the tendency of the deformity to increase from static conditions, and (5) Ankylosis is, therefore, rarer, later, and less extensive than is usually assumed.

Dr. L. A. Weigel said that he had a case of typhoid spine under his care at the present time which seemed to show that there might be actual bone disease and bone destruction.

Dr. N. M. Shaffer characterized the region of the spine from the seventh vertical to the tenth dorsal vertebræ as the region of bad results.

Dr. H. P. H. Galloway said that he had seen at least one case of Pott's disease in which two distinct and separate regions of the spine had been affected. The patient was a woman of about twenty-six years, with disease in the mid-dorsal region, and with a distinct kyphos in the lower lumbar region.

Dr. Harry M. Sherman said that there were certainly border-line cases between typhoid fever and tuberculosis as regards the effect on the spine, and that sometimes the orthopedic surgeon would be called upon to differentiate between these two diseases.

Dr. C. F. Painter said that he could recall at least two or three cases of double vertebral kyphos. In the absence of bacteriological evidence of typhoid fever, and possibly also in the absence of a positive Widal reaction, one should be extremely cautious about accepting these cases as of common occurrence.

Dr. Henry Ling Taylor remarked that in making the diagnosis of two foci of disease one should be very careful to remember that when there is a kyphos in the upper dorsal region there is apt to be a compensatory kyphos in the lumbar region.

Dr. Freiberg said that in his case there was not that degree of muscular rigidity, extending for a considerable distance above and below the lesion, that one would expect if the disease were vertebral tuberculosis.

The Mechanical Treatment of Internal Derangement of the Knee-Joint.—Dr. Frank E. Peckham of Providence read this paper. He said that when the leg was partly flexed the ligaments were relaxed, and any twisting of the tibia at this moment might allow of slight separation of the joint surfaces, and so permit of a locking of the joint. The treatment should consist of rest in bed with massage or the use of a stimulating liniment. A second attack of this kind should lead to the application of an apparatus which would cause lateral pressure to be made upon the inner condyle and prevent twisting of the tibia. He had used with great satisfaction an apparatus for this purpose devised by Dr. Shaffer. Several illustrative cases were reported.

A Case of Osteoma of the Knee-Joint.—Dr. R. Tunstall Taylor of Baltimore reported this case, and exhibited the specimen and skiagraphs. The patient was a girl of fourteen years, who, after slipping on the sidewalk, found herself unable to straighten the knee. She had been treated without effect for two years or more before coming to him. The stereoscopic skiagraph showed a foreign body between the condyles. This was removed by operation, and was found to be an osteoma.

The X-Ray Stereoscope.—Dr. L. A. Weigel of Rochester exhibited this instrument and described it. In using it two exposures are made with the *x*-ray tube in two different positions with reference to the subject photographed. The distance between these two positions of the *x*-ray tube should not be much over the distance between a person's eyes, otherwise distortion will result. The two negatives thus obtained are placed in a reflecting stereoscope and combined so as to form a single image, which appears to the observer in relief. This method enabled one to localize more accurately the objects found in skiagraphs.

Report of a Case of Fracture through the Site of an Excised Knee-Joint.—Dr. H. P. H. Galloway reported this case. The patient was a man of forty years, who, nine months after an excision and as a result of a misstep, threw the weight of the body suddenly upon the stiff leg, and in consequence sustained a fracture through the excised joint. After rest for a time there was such a large effusion of blood that this was removed by aspiration. The limb was encased in plaster until a union had been effected, and since then there had been no trouble.

The evening was devoted to demonstrations of methods and appliances of use in connection with the plaster-of-paris bandage.

Second Day.—Friday, June 6.

The Diagnosis of Hip Disease.—Dr. Robert W. Lovett of Boston presented this paper. The author analyzed ninety-five cases of hip disease, beginning in 1897 and 1898, as to their condition four years later. About two-thirds of the cases proved to have been real destructive tuberculous bone disease pursuing a characteristic course. About twenty-three cases had recovered rapidly without much treatment, and had remained entirely well. A group of fifteen miscellaneous cases proved to be infantile paralysis, arthritis deformans, coxa vara, etc., and did not pursue the characteristic course of tuberculous disease. The symptoms presented by the different groups were analyzed and the conclusion reached that the diagnosis could not, as a rule, be made offhand from certain symptoms generally considered to be characteristic, but only with great care and often only after considerable observation.

The Rational or Combined Treatment of Coxalgia.—Dr. R. Tunstall Taylor read this paper. He said that after giving a trial to all of the operative methods suggested he had found that many of them were disappointing or useless. The paper dwelt particularly upon the value of erasion. He had found the *x*-ray exceedingly useful in pointing out tuberculous lesions of the hip-joint seen in the early stage, and he considered it vastly superior to the tuberculin test, as it was safer and freer from sources of error. The affected portions look much paler in the skigraphic negative than the surrounding bone, and such a negative afforded an excellent guide for early operation for the removal of the disease focus. He was disposed to look upon the dissemination of tubercle as a bugbear, especially when care was taken to reach the disease focus by the least bloody route. If erasion were practised, the objection that the growth of the limb would be arrested would not apply, as in the case of an excision. An ankylosed hip-joint, obtained at once, seemed to him preferable to a diseased and discharging joint for years, with ultimate ankylosis. There was as yet no available statistics for the operation of erasion practised in this manner. After the operation the patient should be placed in bed with traction in the line of deformity. In cases in which the disease focus is very small, rest, fixation, and traction might be employed in the hope that nature, supplemented by proper hygienic measures, would effect an arrest of the disease, but skiagraphs should be taken from time to time to determine the exact condition present. On the other hand, if the skiagraphs showed the presence of extensive disease, erasion offered no advantages. This operation was suitable only for cases showing moderate bone involvement. The disease focus having been found by the aid of skiagraph, it should be removed with the round irrigating curette, and the wound irrigated with a disinfectant solution. He had tried carbolic acid and alcohol in some cases, but had abandoned them after seeing a child die almost immediately on the table from acute carbolic acid poisoning arising, probably from the carbolic acid having directly entered a large vessel. The solution he preferred now to use was a 2½ per cent. solution of formalin. A wick of iodoform gauze was used for drainage, and the wound was closed with silver wire. After the operation a traction force of five pounds should be used.

The Remittent Limp of the First, Apparent Stage of Hip-Joint Disease.—Dr. NEWTON M. SHAFFER presented this paper. He said that as long ago as the meeting of this association in 1889 he had spoken of this remittent limp as well known, but had found then, and since, that this symptom had not been very generally appreciated. He had known as many as seven attacks of limping to occur before the symptoms of hip-joint disease became sufficiently acute and urgent to lead to the diagnosis of disease of that joint. He had found, moreover, by careful study that although the limp is remittent, the reflex muscular spasm does not wholly disappear in the intervals.

The Operative Treatment of Hip-Joint Disease.—Dr. JAMES K. YOUNG of Philadelphia presented this paper. Under the head of operative measures for the correction of deformity, the author mentioned: (1) Multiple myotomy and tenotomy; (2) Forcible straightening, and (3) Osteotomy. The first two, he said, were not effective unless combined. The best method of performing osteotomy, in his opinion, was that recommended by Gant. After the operation on double cases the limbs should be placed in a straight position. The operative measures for arthritis were divided into: (1) Aspiration; (2) Simple incision; (3) Erasion by Willard's method; (4) Excision, and (5) Amputation. The operation of erasion had been found very satisfactory, particularly in children, and should be performed in preference to excision. The latter was appropriate in cases of long-continued suppuration with extensive bone change, especially when associated with albuminuria. He considered the external curvilinear incision used by Agnew preferable in most cases of excision. The anterior, or Barker, incision had not proved satisfactory except in those rare cases in which the disease was confined to the head or neck of the bone. In all cases in which this anterior incision was employed posterior drainage should be used, and an iodoform emulsion should be injected. Excision should not be resorted to as a routine measure; early excisions were not approved of. The author did not favor amputation at the hip for hip-joint disease except in very rare instances, as, for example, when the disease has extended down the femur and did not involve the ilium to any great extent.

Dr. T. HALSTED MYERS of New York in opening the discussion on the foregoing papers said that he had found most of his errors in diagnosis to have been in connection with rheumatic cases, though certain traumatic cases had also proved confusing. He was sure the statement so commonly made in the textbooks, that articular rheumatism could be excluded in children under five years of age, was erroneous. Before the advent of the *x*-ray surgeons had been in the habit of discounting the effect of traumatism in tuberculous subjects, and insisting that tuberculosis of a joint had developed as a coincidence, but in two of his cases crushing of the neck of the femur, just below the junction of the neck and shaft, had been shown by the *x*-ray, and recovery had taken place in a few months. He had twice made an erroneous diagnosis in cases of coxa vara. In five or six cases, which he had watched for several weeks without being able to make a positive diagnosis, the negative result of the tuberculin test had enabled him to rule out bone tuberculosis, and the subsequent history had proved the correctness of this diagnosis. Of all the signs and symptoms, he looked upon reflex muscular spasm as the most characteristic.

Dr. E. H. BRADFORD thought it was well at present to go rather slowly in the matter of cutting down upon supposed diseased foci in an early stage, for it was not very easy to detect and locate such a focus even with the aid of a skiagram. A very thorough trial of conservative treatment should certainly precede such a radical measure.

Dr. W. R. TOWNSEND of New York recalled two diagnostic mistakes in hospital practice, one a case of sarcoma of the thigh that had been originally diagnosticated as hip-joint disease, and the other a case in which sciatica had been confounded with disease of the hip-joint.

Dr. H. L. TAYLOR thought the experience of most of those present would bear out the statements made in Dr. Lovett's paper. He recalled one instance in which infantile paralysis, during the attack, had been mistaken for hip disease.

Dr. N. M. SHAFFER said that a traumatic separation of the epiphysis might give all the symptoms of hip-joint disease, even to a well-marked muscular contraction.

Dr. B. E. MCKENSIE remarked that rapid recovery did not always exclude joint tuberculosis.

Dr. REGINALD H. SAYRE of New York indorsed what the last speaker had said about quick recovery not being sufficient ground for excluding tuberculous joint disease any more than a quick recovery from incipient pulmonary tuberculosis would justify excluding that condition. He also agreed with Dr. Bradford that the interpretation at the present time of skiagraphs was not sufficiently exact to make him always feel warranted in exploring for and removing disease foci detected by the *x*-ray. He also wished to say that he had several skiagraphs of patients who had recovered from hip disease with excellent motion and without pain, and yet these skiagraphs pointed to an absolutely demoralized joint. In a number of cases he had been unable to detect the difference in the shadows cast by a bone, the seat of disease, and those cast after the person had, according to all the usual evidence, recovered.

Dr. L. A. WEIGEL illustrated the difficulties of interpreting skiagraphs by exhibiting a series of such negatives.

Dr. G. G. DAVIS of Philadelphia said that the measures so far described had been those undertaken with the idea of eradicating the disease focus. There was another procedure, that of drilling the bone in several places in the acute stage of the disease. He had practised this method, and was of the opinion that in this way the course of the disease could be materially influenced by an operative procedure, which was not grave, which did not entail any mutilation, and which was not so radical and dangerous as the operations for the absolute removal of the diseased parts. The ordinary appliances and conservative measures were, of course, necessary in connection with this operative treatment.

Dr. JOHN DANE thought that many cases diagnosed as tuberculous were really syphilitic.

Dr. H. M. SHERMAN said he had been accustomed to look upon cases presenting persistent atrophy of the limb as really tuberculous. Erasion of the hip, a deeply buried joint and one difficult of access, seemed to him an operation that must be even more disappointing than erasion of the knee. He was of the opinion that the limp or hip disease was due to destruction of bone.

Dr. JOHN RIDLON remarked that even after there had been extensive bone destruction the examination with a radiograph might be negative because of the absence of bone deposit. On the other hand, if the bone had been deposited, the radiograph would indicate disease though the patient might have practically recovered.

Dr. Lovett, in closing, said that out of the eighty-eight cases analyzed twenty-one had been of short duration. After three or four years they were well without atrophy, shortening or limitation of motion, and the majority of them recovered after four weeks without treatment. It did not seem to him that from our present knowledge we could say that all, or any large part, of them were tuberculous. About one case in five recovered in a few weeks without treatment. The most significant conclusion, as it seemed to him, was that the ordinary symptoms given in the textbooks as diagnostic of hip disease are not sufficiently accurate to enable us to make, in the majority of cases, an early and accurate diagnosis.

Dr. R. T. Taylor said that the operation that he had suggested was intended more especially for disease of the head and neck of the femur rather than of the acetabular variety, and he agreed with Dr. Weigel that such cases did not yield the best results after operation. In children syphilitic disease was more apt to be in the diaphysis than in the epiphysis. The anterior incision presented no difficulties in technique unless one desired to remove the synovial membrane of the joint.

Wolff's Law of Transformation.—Dr. Albert H. Freiberg of Cincinnati read this paper. It opened with a general consideration of this law, embodying the theory of the functional conformation of bones, and the functional pathogenesis of deformity. By specimens and lantern slides the subject of functional shape was studied in the femora of various animals. Sections were presented from the femora of the ox, sheep, llama, leopard, baboon, and gibbon. The necessity was pointed out for examining into the habits and environments in order to reconcile internal architecture and external conformation. Turning to the subject of functional pathogenesis, a specimen was presented of old, unreduced luxation of the hip, and it was studied in comparison with its normal fellow. It was concluded that Wolff's law and its corollaries, while not admitting of truly mathematical proof, should not be rejected on this account. This law was in consonance with previous observations.

The Treatment of Congenital Dislocation of the Hip.—Dr. Royal Whitman of New York presented this paper. He said that the aim in the treatment should be to stretch thoroughly the anterior border of the capsule, overcome all shortening, and fix the limb in the exaggerated position for a sufficient length of time to permit of retraction of the capsule and muscles. The simple manipulative treatment required in the large proportion of cases to be supplemented by some one of the cutting operations. In many instances the operation of osteotomy was secondary to arthrotomy. If simple manipulation failed, the joint should be explored by incision. If anteversion of the neck were present, the limb should be placed in inward rotation, osteotomy being deferred until the second dressing. Excavation of an acetabulum was formerly thought to be essential, but the field for this procedure was becoming more and more restricted. He favored the application of a short Lorenz spica for many months, and advised that so long as local sensitiveness or pain on use was present the joint should be protected. In general, the more perfect the replacement the greater the danger of restriction of motion. Where excavation had been done success was practically impossible without persistent treatment carried on for years. In a certain proportion of cases of congenital dislocation of the hip it was reasonable to believe that the acetabulum was sufficient at birth. Perfect success could only be achieved by non-mutilating operations, *i. e.* forcible reduction supplemented, if necessary, by arthrotomy or osteotomy. After the open operation there was little excuse for failure. At the last meeting of the Association, held in New York, ten cases of functional cure had been presented, in nine of which the bloodless method had been adopted.

Causes of Relapse after Reduction of Congenital Dislocation of the Hip.—Dr. E. H. Bradford of Boston exhibited a skiagram of a case cured three years ago, and asked those present to pick out which was the abnormal side. The operation had been done by the bloodless method. He did not think it was quite time to tabulate the results; the results after five or ten years were what was wanted in order to be sure that what was taken for a cure might not be a transposition. It was well known that a certain percentage relapse, and the causes of such relapse should be ascertained. For example,if the neck were twisted, unless the foot were kept turned in, the head of the bone would necessarily go out. He was inclined to think that the acetabulum did not require deepening in a very large proportion of cases, although on this point he was still undecided. The speaker urged operation in all cases of congenital dislocation of the hip. He had been disappointed in the results of shortening the capsule.

Dr. John Ridlon said that he had seen in the past ten years about forty cases of congenital dislocation. He believed replacement should be tried repeatedly, using all the force that one dared apply.

Dr. H. M. Sherman said that he had attained a certain measure of success from the reduction of the dislocation through a simple incision, thus making sure that no capsule was interposed. Deepening of the acetabulum would be required in some cases, but was always to be deprecated because of the subsequent stiffening.

Dr. George R. Elliott of New York thought he had found a possible cause of anterior displacement in two cases in the tremendous pressure that he had made posteriorly, thus throwing the bone into the anterior position.

Simplification of the Treatment of Lateral Curvature.—Dr. E. H. Bradford of Boston read this paper. The author took the ground that as the majority of cases were mild and did not result in any very serious disability it was hardly right to take a year of a child's time with gymnastic exercises four or five hours daily. His plan was to carry out a simple treatment within the reach of the general practitioner for a longer period of time. A short bar is placed on blocks and the child lies over this bar and goes through certain exercises, supervised by the mother or nurse. A gaspipe frame with a rod across may be used, and the exercises can be carried out twice daily at home. These exercises are varied according to the region of the spine involved. Having secured the greatest possible flexibility of the spine, the development of the muscles should be begun. To determine the daily progress of the case a medical student in his office had devised a very simple instrument by which the flexibility could be read off in degrees on a dial. Diagrams were exhibited showing the exercises recommended.

Third Day.—Saturday, June 7.

The Necessity of Supporting the Head in Cases of Scoliosis Situated in the Upper Dorsal Region.—Dr. Reginald H. Sayre of New York discussed this subject briefly, illustrating his remarks with photographs, and pointing out that this form of support had been largely neglected because of its attendant inconveniences, but that these were more than counterbalanced by the advantages.

Faulty Attitude and Round Shoulders with Description of an Apparatus for Measuring It.—Dr. Robert W. Lovett of Boston presented this paper. He said that the literature was most unsatisfactory and confusing, and there was no agreement among the various authors regarding the classification of cases. His own method consisted in measuring from a certain horizontal plane anatomical landmarks which were easily found. The middle of the external malleolus is placed opposite the back of the upright of his height-measuring apparatus, and by a slight modification of the sliding horizontal rod the desired measurements could be easily and quickly made. The landmarks chosen were the mastoid, the seventh cervical vertebra, the seventh dorsal vertebra, because it is easily found; the fourth lumbar, because it is opposite the crest of the ileum; the middle of the trochanter, the head of the fibula, and the external malleolus. Measurements taken in this way by the same person at different times and by different persons agree quite closely. Dr. Lovett exhibited a diagram which was a composite of seventy-two healthy boys. He had also had several hundred measurements taken in a girls' school, and the composite of these measurements was very similar to that obtained among the boys, except that the fourth lumbar vertebra was farther forward in relation to the trochanter, due to the relatively greater lordosis found in young women.

Demonstration on a Model of the Connection of Rotation and Lateral Deviation in Scoliosis.—Dr. LOVETT exhibited his flexible model to show that, contrary to the photographs and statements that had been published in the last volume of the transactions by Dr. A. B. Judson, rotation does take place along with the lateral bending.

The Anatomical Changes in Severe Cases of Scoliosis as Demonstrated in the Living Subject.—Dr. L. A. WEIGEL of Rochester discussed this subject with the aid of skiagraphs. He said that the amount of rotation does not necessarily depend upon the degree of lateral curvature. In some of the cases showing marked rotation the changes in the intervertebral cartilages were extreme as compared with the changes in the bone. Attention was also called to the fact that an examination of the skiagraphs in these severe cases made it extremely improbable that any accurate record of the degree of curvature could be obtained by marking the points *supposed* to be the spinous processes.

Operative Treatment of Claw-Hand Resulting from Fracture of the Arm.—Dr. H. P. H. GALLOWAY of Toronto presented this paper. Following the fracture there had been a gradual contraction of the fingers, most marked when the wrist was extended. Examination showed that the flexion of the fingers was evidently due to true shortening of the tendons. An incision was made along the front of the forearm, and the scar of the original injury was separated from the underlying tissues. This did not have any effect on the fingers. Each tendon was then elevated separately and lengthened by transfixing the tendon, splitting it, and allowing the fragments to slip pass each other to the desired extent. An effort was made to form a sheath for the elongated tendons by means of the subcutaneous tissues. The part was kept in plaster of paris for ten or twelve days, and on removing the dressing primary union had occurred. Within a week after this the man had gained free motion, and within a month he could write well and had good grasping power. The functions of the hand were practically normal in two or three months

Fashioning Apparatus for Flat Feet and Deformities of the Toes.—Dr ALBERT H. FREIBERG of Cincinnati presented this apparatus. He said that celluloid had not been found sufficiently strong for use in adults, though sometimes useful in children. It was, however, of some value in the treatment of hammer toe. A pattern of the foot is conveniently obtained by painting the sole of the foot with a mixture composed of 50 parts of a solution of chloride of iron, 45 parts of 80 per cent. alcohol and 5 parts of glycerin. The patient then stands on the card, and the outline of the foot is carefully drawn with a pencil The tracing of the foot may then be developed upon the card by the application of a concentrated solution of tannic acid. This pattern is used as a guide in fashioning a lead model with a horn hammer. It was well to have both the external and internal flanges longer than necessary in the model.

Some Types of Bone Disease Affecting the Vertebral Column Associated with Pressure Paralysis.—Dr. GEORGE R. ELLIOTT of New York reported in this paper several cases, and in addition exhibited illustrative specimens.

A Contribution to Spasmodic Wry-Neck.—Dr. ELLIOTT also presented this paper. He reported a case in which the head was drawn downward and to the right side. Very slight force only was required to restore the head to its proper position. Several neurologists had failed to give her relief. He had made use of a Taylor head-rest, which was exhibited. This apparatus had been worn for two years with the greatest comfort.

The Passive Carrying Function of the Arm; Its Importance; Its Destruction and an Operation for Its Restoration.—Dr. PHIL HOFFMAN of St. Louis was the author of this paper. He pointed out that the normal divergence of the forearms from the body facilitated the carrying of weights. Any injury which caused the articular surface to face downward and slightly inward would necessitate great muscular exertion in weight carrying. This frequently occurred after elbow injuries, but the carrying function could be restored by reversing the plane of the lower articular surface of the humerus. This he accomplished by dividing the humerus above the condyles and bending the lower fragment with the attached forearm outward.

A Back Brace.—Dr. J. C. PEGRAM of Providence exhibited this instrument. The brace consisted of the usual upright and pelvic band, but in addition there were two curved hinged arms passing up in front of the shoulders. These arms are fixed in the desired position by means of a simple confriction joint. A leather strap passes across the front and between these two arms.

A Case of Congenital Absence of the Tibia.—Dr. A. J. STEELE of St. Louis reported this case.

Officers Elected.—*President*, Dr. L. A. Weigel of Rochester; *First Vice-President*, Dr. Reginald H. Sayre of New York; *Second Vice-President*, Dr. R. Tunstall Taylor of Baltimore; *Treasurer*, Dr. E. G. Brackett of Boston; *Secretary*, Dr. John Ridlon of Chicago.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, Held April 9, 1902.

Multiple Diverticula of the Colon.—Dr. J. D. CONDIT reported a case of multiple diverticula of the colon in a woman aged seventy years, who gave a history of a long-standing chronic nephritis with chronic constipation and frequent attacks of bronchitis, extending over many years. The autopsy, which was done in the pathological department of St. Luke's Hospital, by Dr. Wood, showed an hypertrophy of the heart with atheroma of the coronary vessels of the aorta and the smaller arteries, marked emphysema of the lungs and chronic diffuse nephritis. The stomach and the small intestine were normal. In the colon were numerous small diverticula, the largest of which measured about 1½ cm. in diameter. These diverticula were arranged in two irregular rows on either side of the mesenteric border and did not average much over 1 cm. in diameter. They occupied chiefly the walls of the transverse and descending colon, the sigmoid flexure, and the upper portion of the rectum, but there were a few in the ascending colon. They were filled with small hard fecal masses and communicated with the lumen of the gut by a small constricted neck. There seemed to be no connection between these diverticula and the exit of the portal system of the vessels. No enteroliths were found in the diverticula.

The microscopical examination of the diverticula showed that the walls contained the normal coats of the colon. The mucous membrane was somewhat flattened out by pressure; the peritoneal coat was normal. The submucosa was very thin and the muscularis could be seen to cover the wall of the diverticulum, but was reduced to a very thin layer. The mucosa and submucosa were infiltrated with leucocytes, and showed a moderate amount of chronic inflammation. The presence of the muscular coat in the diverticula might be explained by the fact that the protusions from the wall of the coat were still small, and that atrophy of the muscularis had not yet taken place, as is seen in larger diverticula, which measure between 3 and 5 cm. in diameter.

Such diverticula had been recently shown before the Pathological Society by Dr. Hodenpyl, and in his case the muscularis had disappeared. Hansemann had shown that the diverticula of the small intestine appeared chiefly at the site of exit of the intestinal veins from the gut, close to the mesenteric attachment, and that they usually contained no muscular coat, but were hernia of the mucous membrane. In the colon, however, Edel has shown that diverticula were true pouches at first, and that later the muscularis atrophied. They occurred chiefly in the aged and in cachectic individuals, associated with atrophy of the muscular coat and distension of the gut with gas or fæces.

Fibromyoma of the Stomach.—Dr. Condit also presented a specimen of fibromyoma of the stomach. This was an accidental find at the autopsy of a woman, aged sixty years, whose death was due to carcinoma of the uterus with involvement of the rectum and bladder. On the anterior wall of the stomach near the pylorus was a small oval tumor, 2x1x1½ cm., with a smooth surface and sessile base. The tumor was very hard and was adherent to the mucous membrane, but protruded on the outer surface of the stomach. When cut across the tumor was very dense with a capsule which contained the remains of the muscular coat and submucosa. Microscopical examination of the tumor showed it to be composed of irregularly interlacing bundles of fibrous tissue and smooth muscle surrounded by a capsule of connective tissue on the inner surface, and externally blending with the muscularis of the stomach wall. On the portion of the tumor nearest the mucosa there was a moderate amount of inflammation.

These fibromyomata of the stomach wall, Dr. Condit said, are rather infrequent. In 1898 Steiner was able to collect only about fifty-six cases of myomata of the gastrointestinal tract, seventeen of these being in the stomach wall. They were most frequently situated in the lumen, but might be contained in the wall or on the external surface, or finally attached to the stomach by a pedicle. They might be oval and smooth, or irregular and lobular in form. Those containing much connective tissue sometimes showed softened areas and small cysts filled with clear fluid or blood. In a few of the reported cases these cysts had become infected from the bowel and had discharged their contents into the peritoneum with resulting general peritonitis. In a few cases, malignant change of the myomatous tissue had been described with formation of metastases in neighboring lymph nodes; but as a rule these tumors are benign and are discovered only accidentally or at autopsy.

Myoma of the Small Intestine.—Dr. F. C. Wood reported a case of myoma of the small intestine. This tumor was an accidental find in the course of a ventrofixation of the uterus. It was attached to the small intestine, a loop of which prolapsed during operation. This loop was evidently a portion of the lower ileum, but the exact distance from the cæcum to the tumor was not made out. The mass was a lobular, dark, fibrous tumor, attached by a short pedicle to the intestinal wall. It was quite vascular on its surface. The mucous membrane of the intestine was incised around the base of the pedicle, and the tumor thus removed. When hardened it measured 4½x3½x3 cm. The surface was quite sharply lobular and still showed deep blood staining. A cross section of the tumor showed that it was vascular and also contained a number of cysts. The mucous membrane of the intestine was still adherent to the base of the pedicle. Microscopical examination showed the tumor to be largely composed of unstriated muscle and fibrous tissue, evidently arising from the muscular coats of the intestine. The cysts were due to the softening of the surrounding fibrous tissue, and were not lined with epithelium. They contained blood or clear serum.

As Dr. Condit had said, these tumors were rare, especially so in the small intestine, but were of little clinical importance, except for the possibility of their forming traction diverticula, or when provided with a long pedicle, forming a loop about the intestine and so causing obstruction.

Rhabdomyoma of the Testicle.—Dr. Wood also reported this case. The history was that of a young man of eighteen, who had been rather feeble in his youth, but had had no diseases except the exanthemata of childhood. Three months before admission he noticed a swelling in the right testicle. The tumor grew rapidly to the size of a fist, but was not painful, and but slightly tender in the softened areas. When the patient was examined it was found that the tumor had replaced the testicle on the right side and was freely movable in the scrotum. On palpation there were found to be hard and soft areas in the tumor. The softer areas seemed to be in many cases small cysts. The tumor was removed without difficulty and the patient was discharged after a short stay in the hospital. The tumor when hardened measured 11x8x7 cm. It had completely replaced the testicle, but had not extended beyond the tunica albuginea. The remains of the testicle and epididymis were still to be found near the periphery of the tumor, apparently pushed aside by the new growth. The cut surface showed many cysts, the largest ones being between 1 and 2 cm. in diameter. There were also areas of about the same size of yellow, opaque tissue, evidently very cellular. A few very small nodules of cartilage could be seen scattered through the cut section. Microscopical examination showed that the tumor was largely made up of a loose connective-tissue stroma, filled in many places with a very large amount of striated muscle fibers, showing the spindle and spherical forms which are so often seen in embryonic muscle fibers. In only a moderate number of the fibers could striations be made out, but the staining reactions and the arrangement of the nuclei left no question that many of the smaller round masses were muscle cells not cut transversely but remaining undeveloped. The connective tissue stroma also showed an embryonic type, very often cellular and softened, with occasional areas of mucous degeneration. In places the section showed areas of cartilage. In other portions there were epithelial tubules remaining, such as are often found in the teratomata of the testicle. In fact, this tumor might well be classed as a teratoma with excessive development of striated muscle. It did not belong to the group of pure myomata of the testicle, of which about six cases have been collected from the literature.

Sponges Found in Operation Wounds.—Dr. Eugene Hodenpyl reported two cases of sponges remaining in operation wounds, at the same time exhibiting sections and drawings of the lesions with which they were connected. The two cases were illustrative of the experience common to pathologists, that rare cases are apt to occur in pairs ("Binary Occurence of Rare Cases"). As a matter of fact, these two cases came under his notice within a period of seven days. Regarding the rarity of the condition, he remarked that he had not observed this condition before; that his colleagues in the laboratory also had not before seen similar cases. Sections were sent to several other pathologists, none of whom, except Dr. Welch, was willing to hazard a diagnosis. Dr. Welch said that he regarded the peculiar structures as sponge, and based his theory on the recollection of a case of a similar kind which he had seen years ago.

When the cases were studied more carefully the identity of the conditions and the accuracy of this opinion became apparent. The first case was that of a man, seventy years of age, who suffered from epithelioma of the pharynx. Three and a half months before he had been operated on for a primary growth. Directly on the site of the operation, embedded in the connective tissue, he came upon these curious masses, two or three in number. They presented solid threads, often branching and anastomising, and sometimes presenting a double contour, which stained with a large variety of stains. Although "foreign body' was at once suspected, Dr. Hodenpyl was at first thrown off his guard by the fact that the muscle adjacent showed curious degeneration, and it was thought that various phases between the muscle and these curious masses could be traced. The second case was even more remarkable. The patient was admitted to the hospital with a history of recurrence of epithelioma of the lip. He had been operated on eight years before for a primary growth. The appearance of the sections greatly resembled those of the first case, except, as was to be expected, the spicules of sponge showed more evidence of absorption. Many of them were surrounded by giant cells.

Dr. F. C. Wood said that Dr. Hodenpyl's experience had been valuable to him, for shortly after the examination of the specimens referred to, they had a similar case in St. Luke's Hospital; and he would undoubtedly have considered the structure as some kind of degeneration if he had not seen those two cases and had not been instructed by them as to the origin of the condition.

False Diverticula of the Sigmoid Flexure.—Dr. Otto H. Schultze presented a case of false diverticula of the sigmoid fecal abscess, and general septic peritonitis, complicated by purulent meningitis and lobar pneumonia. Dr. Schultze showed a portion of the sigmoid flexure removed from a man about forty years of age, at autopsy. One of the many false diverticula, which contained hard fecal masses, through ulceration and subsequent infection, had given rise to an abscess between the sigmoid and left illiac fossa, which had been ruptured into the peritoneal cavity. No clinical history was obtainable. This condition might account, he said, for some cases of perisigmoiditis, or cases running a course resembling that of appendicitis, the symptoms being referable to the left instead of the right side.

Aneurysmal Dilatation of the Ductus Arteriosus in a Male Infant about Three Weeks of Age.—Dr. Schultze also presented this specimen. The body was found in a school-sink. There were no marks of violence. The ductus arteriosus was dilated and filled with recently clotted blood. Its pulmonary end was closed; its aortic end open and about 7 mm. in diameter. The duct was 2 cm. in length and over 1 cm. in width, thus presenting the condition of a large sacculated aneurysm in the anterior mediastium, bounded on the left side by the left lung, on the right side by the left auricle, coming in relation anteriorly with the left phrenic nerve and posteriorly with the left pneumogastric nerve. Ecchymoses were found on the pleura, pericardium, and pericranium. No foreign material was found in larynx, trachea, or bronchi. The blood was fluid except the recent clot found in the ductus arteriosus. The condition pointed to asphyxia, yet the positive diagnosis of asphyxia by submersion could not be made. It is by no means uncommon, in New York at least, the speaker said, to find that infants whose bodies are discovered under circumstances arousing suspicion as above, may nevertheless have died from natural causes, since many poor and ignorant inhabitants of large cities are not aware that the authorities will bury their dead. It was an open question in this case as to what effect the condition described might have had in causing death by pressure upon the pneumogastric or phrenic nerves. The size of the dilated ductus compared with the size of the anterior mediastium of a three-weeks-old infant is a matter of some importance.

A Case of Conglomerate Tubercles of the Liver, So-called Bile-Duct Tubercles.—Dr. Schultze presented this specimen, which contained, besides many miliary tubercles, a large number of conglomerate tubercles, varying in size from 0.5 to 1.5 cm. in diameter, whose centers were fluid and bile-stained, whose margins were cheesy and surrounded by connective tissue, presenting under the microscope bile pigment and amorphous detritus in the center; then an area of coagulation necrosis, in which miliary tubercles could be faintly made out; and finally tubercle tissue and granulated tissue, in many cases advanced to the formation of fibrous connective tissue. The subject, a male, eighteen years of age, had a most extensive chronic tuberculous bronchopneumonia, with large cavities, from one of which a hemorrhage had taken place, which was the immediate cause of death. The extent of tuberculous inflammation in this subject was most remarkable; the larynx, spleen, almost the entire intestinal tract, peritoneum, bronchial, and retroperitoneal lymph nodes, were affected. Large conglomerate tubercles were found in the spleen and throughout the peritoneum. It seemed less probable that these so-called bile-duct tubercles originated from an infection of the bile ducts than from an erosion or inclusion of the ducts by the process of tuberculous inflammation in the periportal connective tissue.

A Surgical Needle Encysted in the Abdominal Cavity.—Dr. Warren Coleman exhibited a surgical needle which had been found in the abdominal cavity of a young woman. The patient had entered the City Hospital for treatment for alcoholism and chronic nephritis. She died after several weeks. Upon opening the abdomen at the autopsy, the omentum was found to be adherent to the upper part of the bladder. The needle—a curved surgical needle—lay upon the omentum about one inch above the adhesion, with its concavity directed upward, and was completely encysted. It was not until the point of the needle was laid bare that its real nature was determined. The needle measured seven-eighths of an inch from eye to point. A suprapubic hysterectomy had been performed some time previously—probably a year or more, judging from the appearance of the scars—and the needle had been left in the abdominal cavity.

Proteosoma Malaria in Sparrows.—Dr. W. N. Berkeley submitted specimens and described the results of some work he had done in September, 1901, on the subject of malaria in birds. It was easy in the Bronx Borough to find English sparrows (Passer domesticus) infected with malarial parasites corresponding in all morphological characters with the proteosoma of Labbé.

Dr. Berkeley had examined many hundred birds, of which 75 per cent. were infected slightly and 15 per cent. severely. The latter, though apparently well when in the open, sickened rapidly in confinement, refusing to eat, and sitting with ruffled feathers in a corner of the cage.

The temperature of one bird reached 108.8°F., though the speaker would not venture to say that this figure represented an unusually high fever in birds. The heart-blood of one bird, examined post mortem, showed many red cells invaded by five to seven sporocytes, apparently a multiple infection. He had not found similar observations recorded in the literature, and was not able to claim that this form of infection was of proteosomal nature.

Persistence of Varieties of the Bacillus Diphtheriæ and of Diphtheria-like Bacilli.—Dr. Anna N. Williams presented this paper, the outline of the work being as follows: (1) A study of the diphtheria and diphtheria-like bacilli found in a series of clinically typical diphtheria at the hospital for contagious diseases; (*a*) Serial smears of cultures directly from throats and noses; (*b*) Pure cultures isolated from these cultures. (2) A study of the diphtheria and diphtheria-like bacilli found in healthy and diseased throats in a town during an epidemic of diphtheria; (*a*) smears of cultures directly from throats; (*b*) pure cultures isolated from these cultures. (3) A study of diphtheria and diphtheria-like bacilli found in sore throats during an epidemic of diphtheria at a home for destitute children; (*a*) pure cultures. (4) A study of pure cultures of diphtheria and diphtheria-like bacilli from sources other than those given above; (*a*) on various artificial culture media grown under various conditions; (*b*) in living tissues of guinea-pigs, white rats, and goldfinches; (*c*) in symbiosis with other bacteria.

The results obtained from these studies was summarized as follows: 1. (*a*) In a series of ten cases of clinically typical diphtheria only one variety of the specifically-virulent diphtheria bacillus was obtained from the throat of each case throughout the course of the disease and until suspicious bacilli disappeared; (*b*) from different parts of the same patient only one variety of specifically virulent diphtheria bacillus was obtained; (*c*) "pseudo" varieties were found no more frequently at the end than at the beginning of the disease; (*d*) pure cultures continued to show the characteristics similar to the original culture for many culture generations. 2. (*a*) Under normal conditions different varieties of diphtheria-like bacilli might be found in the same throat; (*b*) many throats in a single institution might contain many diphtheria-like bacilli with no case of diphtheria resulting; (*c*) there were many distinct varieties of diphtheria-like bacilli, all of which in several pure cultures retain the characteristics of the original culture. 3. (*a*) In each case of diphtheria apparently contracted from the same source, the same variety of virulent diphtheria bacillus was found; (*b*) this variety remained the only variety of virulent bacilli found until its disappearance; (*c*) no gradations in "pseudo" types were found—the same type seen in the first examination continued to be present in later ones; (*d*) pure cultures continued to show characteristics similar to the original cultures for many culture generations. 4. (*a*) Some cultures when grown on artificial media showed certain changes, but each culture changed in its own way, retaining its distinct individuality. After many culture generations, however, especially when transplantations were made at short intervals, the different varieties of the specifically virulent diphtheria bacillus tended to approach each other or rather to run in lines with a common norm; (*b*) no non-virulent morphologically typical bacillus has been made virulent, neither have solidly staining "pseudo" varieties or other atypical varieties been made virulent or morphologically typical.

These studies seemed to demonstrate that the morphologically typical diphtheria bacillus is a distinct species from the atypical diphtheria-like bacilli and so-called "pseudo" forms; and that it has many true morphological varieties of sub-species, which, while showing transitory ontogenic variations due to change in environment and life habit, have more or less persistent phylogenic characteristics, which reappear when the organism is placed in a previous environment.

Dr. William H. Park, in discussing the paper, said it was really extraordinary how the characteristics of different bacilli had been found to persist for long periods when changed from one culture medium to another and then restored to their original medium. He believed that many of the changes reported in the literature on the subject were due to errors in the observations. One thing that particularly interested him was the fact shown by the observations at the Willard Parker Hospital, that, whereas the diphtheria bacilli apparently differed in virulence at different times when tested in bouillon, in reality they differed only in their rate of growth, and were very much alike when tested in ascitic bouillon. The probability was that in the throat they were all very much the same in respect to virulence. The practical conclusion which they were entitled to draw from the investigation was that when bacilli began by being virulent, they remained virulent to the end; and on the other hand that if they were not virulent at the start, they would not become so. This being so, it seemed that there was no use of the physician making repeated tests in any one case, with the view of ascertaining the degree of virulence the bacilli showed. Summing up, he said that the observations seemed to establish beyond doubt that the bacillus did not change from one type to another. The experiments had been most carefully conducted, and he believed that the conclusions arrived at were correct.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending August 2, 1902:

	Cases.	Deaths.
Measles	98	7
Diphtheria and croup	186	19
Scarlet fever	91	7
Smallpox	4	5
Varicella	11	..
Tuberculosis	223	134
Typhoid fever	63	8

The Etiological Significance of the Acid-Resisting Group of Bacteria and the Evidence in Favor of Their Botanical Relation to Bacillus Tuberculosis.—The conclusions offered by A. C. Abbot and N. Gildersleeve are as follows: (1) That the majority of the acid-resisting bacteria may be distinguished from true tubercle bacilli by their inability to resist decolorization by a 30 per cent. solution of nitric acid in water; (2) That some of the acid-resisting bacteria are capable of causing in rabbits and guinea-pigs nodular lesions suggestive of tubercles; that these lesions, while often very like tubercles in their histological structure, may nevertheless usually be distinguished from them by the following peculiarities: (*a*) When occuring as a result of intravenous inoculation they are always seen in the kidneys, only occasionally in the lungs, and practically not at all in the other organs; (*b*) They constitute a localized lesion, having no tendency to dissemination, metastasis, or progressive destruction of tissue by caseation; (*c*) they tend to terminate in suppuration or organization rather than in progressive caseation, as is the case with true tubercles; (*d*) they are more commonly and conspicuously marked by the actinomyces type of development of the organisms than is the case with true tubercles, and these actinomyces are less resistant to decolorization by strong acid solutions than are those occasionally seen in tubercles; (3) That by subcutaneous, intravenous and intrapulmonary inoculation of hogs (4) and calves (15) the typical members of the acid-resisting group are incapable of causing lesions in any way suggestive of those resulting from similar inoculations of the same animals with true tubercle bacilli; (4) That though occasionally present in dairy products, they are to be regarded as of no significance, etiologically speaking, but may be considered as accidental contaminations from the surroundings and not as evidence of disease in the animals; (5) That the designation "bacillus" as applied to this group of bacteria and to the exciter of tuberculosis is a misnomer; they are more correctly classified as actinomyces. —*University of Pennsylvania Medical Bulletin.*

Sciatica and Its Treatment.—Seth C. Felt dissolves one grain of atropin in one hundred drops of distilled water, accurately measured by a dropper held in a perpendicular position. He begins treatment by giving three drops hypodermatically about four inches above the patella in the sciatic limb, at bedtime; in twenty minutes the effects will be marked, pulse 120, pupils dilated, head dizzy, with an intolerable thirst. If the above symptoms subside within twelve hours, the dose was not sufficient and it can be increased one drop each time, until the dizziness lasts twenty-four hours. The dose must not be repeated oftener than once in forty-eight hours, and not until the head symptoms have entirely disappeared. The total number of cases treated by the writer (one being himself) is twenty-nine, with twenty-two permanent cures. Since describing his treatment he has been met with nothing but opposition from the profession, which he attributes to timidity and lack of confidence. He acknowledges that the temporary effects of the heroic doses are severe and unpleasant beyond description, but considers them worth going through with, in order to obtain the cure of this most painful disease.—*The Physician and Surgeon.*

The Stokes-Adams' Syndrome, with Report of Two Cases.—Frank Billings says that the phenomena which characterize the disease consist of a permanent slow pulse with attacks of giddiness or faintness, or transient unconsciousness, or of epileptiform convulsive seizures. Attending these characteristic symptoms is usually a subjective breathlessness or dyspnœa, and the patient is often pale, especially just before an attack of unconsciousness. There may attend any of the phenomena usually associated with cardiac and blood-vessel disease, as various degrees of angina pectoris, Cheyne-Stokes' phenomenon, cardiac asthma, or perhaps some permanent signs of cardiac failure in the way of venous congestion of lungs or of abdominal organs with dropsy. The prognosis is uncertain, and depends entirely upon the basic cardiovascular disease. The treatment should be based on the cardiovascular condition. The nitrites and iodides frequently give relief to the syncopal attacks. Digitalis has been known to quicken instead of slow the heart. French writers report marked improvement in cases treated by a milk diet. During the paroxysm the nitrites with diffusible stimulants are the most beneficial.—*Medicine.*

The Parasitology of Malignant Growths (Syncytioma Malignum).—J. George Adami draws the following deductions from his study of the subject: (1) There exists one form of tumor of highly malignant type in which the infiltrating cells are not those of the organism itself but are derived from another organism. The development of the syncytioma must be attributed to either an increase in the invasive properties of the syncytial cells, or a lessened resistance on the part of the maternal tissues or a combination of the two. If microparasites play any part in the production of the tumor, that must be either by exalting the infiltrative powers of the one or by lowering the resistant powers of the other. Proof positive of the existence of such specific microparasites is still wanting. Admitting that microparasites and their products are capable of inducing cell-proliferation, we must also admit that other external agencies have the same capacity, so that that microparasites, at most, may be one of the causes of aberrant cell growth. The prevalent conception of cancer parasites, as existing within the cancer cells, involves the idea of malignant growths being the product of parasites acting within parasites, or as shown by this study of the syncytioma the tumor cells themselves are essentially parasitic in the organism.—*The Clinical Journal.*

The Diagnosis of Malaria by the Practitioner in Non-Malarious Country.—Patrick Manson emphasizes the importance of a thorough reliance on the three classical methods of diagnosing malaria: The clinical—tertian and quartan periodicity; the therapeutic—the curative effect of quinine; and the microscopical—the detection of the parasite or its products in the blood, and the characteristic leucocytic variation. A thorough and intelligent application of one or all of these methods seldom if ever fails to lead to a correct diagnosis for or against malaria. At the same time he warns the practitioner that, although a positive diagnosis of malaria may be indicated in some given case, the presence of malaria does not exclude other diseases. On the contrary, malaria often predisposes to other diseases. Similarly, the explosion of a latent malaria is favored by other infections, especially typhoid and tuberculosis.—*The Clinical Journal.*

Five Cases of Conjugal General Paralysis.—P. Kervanal and G. Raviart report five instances in which both husband and wife were affected almost simultaneously with general paralysis. In the first observation syphilis seems to have been the sole cause, in the second it is a question whether syphilis was present or not. Alcoholism was the chief element in the third case, while in the fourth there was no syphilis nor alcoholism, but the cerebral troubles in the husband appear to have been due to cerebral traumatism, while in the wife they were attributable to grief and poverty. In the fifth instance heredity in the husband and grief and anxiety in the wife were the causes. In four cases the man was the first affected, in one case the woman.—*Archives de Neurologie.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended August 2, 1902:

PELVIC DEFORMITY IN NEW YORK.*

By JAMES CLIFTON EDGAR, M.D.,
NEW YORK.

Definition.—While our conception of a contracted pelvis is that of Michaelis, Litzmann, and others, who considered a pelvis contracted when one or more of its diameters is so shortened as to lead to an abnormal mechanism of labor without necessarily retarding the delivery of the child, and that of Litzmann, who looked upon all generally-contracted pelves as having contracted a conjugata vera of 3¾ inches (9.5 cm.) or less, and all flat pelves having a conjugata vera of 4 inches (10 cm.) or less, still we have in these cases followed the example of Williams, and used the diagonal conjugate as the clinical index of the pelvic deformity, and classified as contracted all flat pelves having a conjugata diagonalis of 4.33 inches (11 cm.) or less, and all generally contracted pelves having a diagonal conjugate of 4½ inches (11.5 cm.) or less. I have included among the thirty generally-contracted pelves four cases in which the diagonal conjugate was, respectively, 4¾ inches (12 cm.); likewise among the fourteen flattened pelves, five cases in which the diagonal conjugate was in four instances 4½ inches (11.43 cm.), and in one 4¾ inches (12 cm.). These nine cases have been included, although exceeding the limits of our definition, since the previous and present history and the other pelvic measurements pointed toward a justification of their inclusion. In all of my cases the external pelvic measurements were taken with a Baudeloque pelvimeter, and the diagonal conjugate was measured with the finger in the usual manner, and in many instances with the Farabœuf pelvimeter in addition. Pelvimetry does not lead to mathematically accurate results. In minor degrees of contraction it is impossible to say in advance whether or not intervention will be necessary. Certain factors enter into every case which are beyond our powers of calculation, as size and shape of the fetal head, compressibility and power of moulding, character of labor pains, and resistance of soft parts. Still it is always possible to know the size and shape of every pelvis, and thereby to be in a position to explain the indication for the various operations. In pelves of the same measurement one patient may be delivered spontaneously, while with the next we are obliged to resort to operative intervention. However, pelvimetry is none the less a necessity. An argument for the greater accuracy of our measurements is to be found in the fact that all the cases were used for clinical instruction, and often repeatedly measured by different observers during pregnancy. Several of the cases were remeasured while under an anæsthetic in subsequent clinical demonstrations. Another series of cases of pelvic contraction from one thousand cases of confinement at the New York Maternity, tabulated after many hours of labor, I have had to abandon since the accuracy of the pelvic measurements was questionable, there being no verification of the measurements originally taken.

Material and Findings.—My conclusions are drawn from 1,200 consecutive cases of confinement occurring in the service of the Mothers' and Babies' Hospital, New York. The bound histories of these cases have been presented to the New York Academy of Medicine, and hence are available at any time for inspection; the confinement number of the tables herein printed correspond with those of the bound histories; four hundred of the cases were hospital or in-door patients, and 800 dispensary or out-door patients. Among the 1,200 cases I found, according to our definition, thirty cases of generally-contracted pelves and fourteen cases of flattened pelves. The histories do not warrant us in distinguishing between rachitic flat and simple flat pelves. Among the 1,200 consecutive labors there were no irregular forms of contraction, as osteomalacic, obliquely contracted coxalgic, spondylolisthetic, or kyphotic. This gives us forty-four contracted pelves among 1,200 cases observed, as follows:

Forty-four deformed pelves in 1,200 cases equals one in 27.27 cases, or 3.66 per cent.

Thirty generally contracted pelves in 1,200 cases equals one in forty cases, or 2.50 per cent.

Fourteen flattened pelves in 1,200 cases equals one in 85.71 cases, or 1.16 per cent.

Race.—The racial distribution of our 1,200 cases studied was as follows:

Americans	499	or	41.58	per cent.
Irish	215	"	17.91	"
Russian	130	"	10.83	"
German	105	"	8.75	"
English	35	"	2.91	"
Austrian	23	"	1.91	"
Italian	20	"	1.66	"
Hungarian	16	"	1.33	"
Scotch	14	"	1.16	"
Swedish	12	"	1.00	"
Canadian	8	"	0.66	"
Polish	7	"	0.58	"
West Indian	6	"	0.50	"
Roumanian	6	"	0.50	"
Bohemian	6	"	0.50	"
Swiss	4	"	0.33	"
Danish	4	"	0.33	"
French	2	"	0.16	"
Cuban	2	"	0.16	"
Turkish	1	"	0.08	"
Norwegian	1	"	0.08	"
No record (30 blacks)	84	"	7.00	"
Total	1,200 cases.			

Of the 1,200 cases 1,170 were white and thirty black. Of the thirty blacks three (C. H. 355, 599 and 769) are found in our list of deformed pelves, all three generally contracted.

The forty-four deformed pelves were distributed as follows:

Americans	20	Swiss	1
Irish	9	Austrian	1
Black	3	Russian	2
West Indian	2	Hungarian	2
German	2	Canadian	1
English	1		
Total			44

---

*Read at the twenty-seventh annual meeting of the American Gynecological Society, held at Atlantic City, May 27, 28 and 29, 1902.

The thirty generally contracted pelves were distributed as follows:

Americans	14	Hungarian	2
Irish	5	Russian	2
Black	3	Austrian	1
West Indian	2	Canadian	1
Total			30

The fourteen flattened pelves were found among:

Americans	6	English	1
Irish	4	Swiss	1
Germans	2		
Total			14

Para and Age.—I found that twenty-four of the cases were I-para; seven were II-para; three were IV-para; two were III-para; three were VI-para; two were V-para; one was VII-para; one was IX-para, and one was XII-para.

The ages, as will be seen from the tables, ranged from sixteen to thirty-nine years.

Previous History.—Of the thirty generally-contracted pelves eighteen were primigravidæ or primiparæ, and of the remaining twelve four had had previous instrumental deliveries. One case (C. H. 512) having had as many as three. Of the fourteen flattened pelves, six were primiparæ or primigravidæ, and of the remaining eight four had had previous instrumental deliveries; one (C. H. 356) had three forceps' operations previously; one (C. H. 161), symphyseotomy; one (C. H. 117), once forceps and once symphyseotomy; and one (C. H. 304), one forceps' operation.

Presentation and Position.—Of the forty-four cases there were forty vertex presentations, two abortions, and two of which there was no record. All the vertex presentations were anterior positions, with the exception of three posterior. There were two twin cases, the second fœtus in each case presenting by the breech. The three posterior vertex presentations were all among the generally-contracted pelves.

Character of the Labors.—Thirty-one of the forty-four labors were spontaneous and thirteen operative. The operations were: Ten forceps; one induction of lapor and forceps; one podalic version, and one craniotomy.

Result for the Mothers.—The maternal mortality was *nil.* An uneventful puerperium resulted in forty-one of the forty-four cases. In one pleurisy with effusion occurred, and in two, mild sepsis.

Result for the Children.—Of the forty-four cases there was but one still-birth; two were abortion cases, and two twin labors, leaving forty-three living children at term.

Frequency of Pelvic Contraction in Different Countries Compared.—While much statistical matter on this subject is available, it can hardly be said as yet that we possess any trustworthy information on the subject as a whole, nor can any gain be made in this direction until some standard of agreement is reached by obstetricians throughout the world. Not only is there absence of harmony in measuring these pelves, but there is even failure to agree upon what a contracted pelvis really is. Litzmann's measurements, which are supposed to underlie most statistics, are certainly often disregarded in favor of some personal standard; while some tables are based upon the actual measurements of the diagonal conjugate from which the true conjugate is obtained by subtraction. Some obstetricians, like Leopold, are said to take only external measurements, which appears to give an abnormally high percentage of contraction (24.3). It can be readily shown that this is a very fallacious method of arriving at the dimensions of a contracted pelvis. Some observers, Reynolds, Flint, and others, estimate the prevalence of contraction by the proportion of cases which require operative intervention during delivery. The abnormally small percentages obtained by this method are not surprising in virtue of the demonstration that the great majority of technically-contracted pelves do not necessarily occasion any disturbance of labor (Krönig, Valency, and others). It is obvious that to secure uniformity direct pelvimetry should be employed, using the Skutsch or Farabœuf apparatus under uniform conditions; also that all the women who come to a clinic should be measured, and not alone those in whom there is a suspicion of contraction. There should be two species of contraction recorded; absolute and relative; but nothing will be gained by subdividing the relative cases according to the length of the conjugate. On the other hand, it would be of value to subdivide the relative cases in regard to the character of the labors and kind of intervention indicated. The continental statistics cited by Williams and Dobbin do not appear to possess any direct value for the purposes of comparison, or even for throwing light upon the relative frequency of contraction in different countries. The method by which the results were obtained is seldom alluded to. Of interest to note is the very large percentage of contraction in which the course of labor was undisturbed, several authors reporting about 70 per cent., each, with this termination. The recent work at the Paris and Leipzig clinics upon labor in contracted pelves shows that this percentage obtains to-day as well. Reynolds did not measure his cases unless an impediment arose to labor. The following comparison appears to show how the unlike results of two different clinics might be brought in harmony very readily. Reynolds reports a series of 2,227 labors in which he had to interfere for contracted pelvis in some thirty, or 1.34 per cent. He does not record the percentage of contraction in which intervention was not necessary, but if his percentage of technical contraction was as high as that of Pinard, Michaelis, Leopold, and others, he should have had about 100 cases of technical contraction, or 4.5 per cent. Williams states that Reynolds should have had about 6.8 per cent. technical contraction, which agrees closely with his own figures for white women (7.1). Pinard, in 2,000 labors in a given series, found 107 cases of technical contraction, or over 5 per cent. These figures show considerable similarity. Flint of New York, in about 10,000 labors, found about the same percentage of contraction as Reynolds (1.42). If he obtained his percentage in the same way, no further comment need be made. Williams appears to believe, however, that the figures were obtained by general pelvimetry, and seeks to explain the small proportion of technical cases on the ground that the great majority of his patients were East Europeans, 75 per cent. alone being Russians, which of course, means Hebrews. He recalls the fact that Hugenberger found but 1.2 per cent. contraction in Russians; but if contracted pelves are the outcome of misery, semi-starvation, exposure, etc., the people of Eastern Europe would hardly be exempt. It is much simpler to explain such discrepancies by want of harmony of method, etc. On the other hand, there can be no doubt that the proportion of technical contraction in Central Europe is higher than the figures obtained in America and France. The percentage estimated by Winckel (10-15) appears to be borne out by the work of Michaelis and Litzmann, the estimate of Schauta, and many other statistics. Schauta's statement, that one woman in seven in Vienna had a certain amount of con-

traction should go far to offset the much lower figures of Braun and Herafeld, Ludwig and Savor, etc. This higher percentage of contraction in Central Europe is generally admitted, and is explained in some quarters by the great prevalence of rickets and osteomalacia. Another element, which is perhaps ignored, is the habit of the German peasant women of doing men's labor, which would tend to make the pelvic bones thicker and diminish the size of the cavity. Contraction thus produced might be offset by the superior muscular development of such women. In England, judging from the small number of craniotomies at some of the maternities, the obstetricians of that country believe that contracted pelves are becoming very rare. General sanitation directed to promote the welfare of the poor is believed to be responsible for this amelioration, and Germany is declared to be remiss in this respect. The question of contraction in the British Isles cannot be settled off-hand in this manner, and it must be remembered that Spiegelberg once accused the English of neglecting the study of pelvic contraction. In America Williams' total material, including many negroes, shows 13.1 per cent. technical contraction against 7.15 for white women alone. The frequency of contraction in the negro is two and one-half times that seen in the white race, and, as the colored women live largely under the most unfavorable hygienic conditions, they are enabled to swell the percentage of contraction just as very probably happens with a certain class of Central Europeans.

England.—At the meeting of the International Gynecological Congress, Geneva, 1896, F. Barnes of London reported 38,065 cases of labor, all measured by the same method of pelvimetry, and found but 195 cases of contraction, or 0.5 per cent. At the meeting of the same Congress in Amsterdam, 1899, he also stated that in 40,000 deliveries at the Royal Maternity, London, there were no indications for cæsarian section, and but fourteen craniotomies. In his "Obstetric Medicine and Surgery" page 762, he attempts to explain this low percentage. The poorer classes in England are better fed, housed, and clothed than on the continent, where rickets and osteomalacia are much more common. Both Barnes and Radford believe that the prohibition of child labor in factories has greatly diminished the frequency of contracted pelves in England.

France.—At the Geneva Congress, 1896, Fochier reported for Lyons and vicinity 21.11 per cent. of contraction. Pinard noted ninety-five cases of contraction in one year at the Baudelocque Clinic, in a material of about 2,000 (about 5 per cent.) labors. In Budin's statistics at the Tarnier Clinique, April, 1898, there were 233 cases of contraction in 3,381 labors—a fraction less than 7 per cent. In another series of Budin's (period, etc., not known, there was 8 per cent. contraction in between 7,000 and 8,000 cases. Bormani once found 16 per cent. in a series of 715 cases of Tarnier's. He also appears to obtain a similar figure from averaging the percentages of others.

Germany.—At the Geneva Congress, 1896, Doehrn (Königsberg) placed the percentage for that country at about twelve, which agrees well with Winckel's estimate of ten to fifteen. Individual statistics vary from eight or nine to nearly twenty-five. The highest measurements were obtained by Leopold, who used external measurements largely.

Switzerland.—At two Swiss clinics the percentages obtained were respectively sixteen and eight.

Austria-Hungary.—Paulik, at the Geneva Congress, reported nearly 30,000 labors with 7.08 per cent. contractions. Ludwig and Savor, confining their statistics to a single clinic in Vienna, during fifteen years obtained a percentage of contraction of 3.83. Similarly, Knapp, confining his figures to a clinic at Prague for four years, obtained a percentage of contraction of but 2.44. Schauta of Vienna estimates that 14 per cent. of pelves are contracted.

Russia.—Hugenberger of St. Petersburg has a percentage of but 1.2; while Buchholz of Dorpat, gets 5.1 per cent.

Italy.—At the Geneva Congress, 1896, Pestalozza reported 18.13 per cent. contractions as determined by pelvimetry and the course of labor, in a material of nearly 8,000 cases.

Holland.—Treub of Amsterdam reports (Geneva Congress) a frequency of 3.51 per cent. of contractions.

United States.—Reynolds found thirty cases of contraction requiring operative intervention in 2,227 cases. The percentage thus calculated would be but 1.34, but this author thinks that with routine pelvimetry and inclusion of all mild degrees the percentage might be brought up to 6.8. At the Johns Hopkins Hospital 1,000 women were measured, nearly one-half being negresses. The number of cases of contraction was 131, or 13.5 per cent. This was so distributed that the percentage for white women was 7.14 and that for negresses 19.83. The number of cases requiring operative treatment was forty-six, or 35.11 per cent. (4.6 per cent. of the entire number), subdivided as follows: Forceps, twenty-one; version, fifteen; extraction, four; symphyseotomy, two; mutilating operations, four. The Johns Hopkins material comprised seventy-nine generally contracted, twenty-five simple flat, and twenty rachitic pelves, while seven were examples of irregular forms of contraction. Flint found but 1.42 per cent. contraction in 10,223 women confined at the New York Lying-in Hospital. Crossen of St. Louis found 7 per cent. contraction in 800 cases. The late Dr. Lusk taught that pelvic deformity was of rare occurrence among native-born American women, while rachitis and osteomalacia are unknown. Hirst holds that we have markedly underestimated the frequency in this country.

Conclusions.—1. Of our 1,200 consecutive cases measured 499, or 41.58 per cent., were American-born women; 215, or 17.91 per cent., Irish; 130, or 10.83 per cent., Russian; 105, or 8.75 per cent., German; 30, or 2.50 per cent., black, etc. (See page 241).

2. Contracted pelves occurred in forty-four cases, once in twenty-seven cases, or in 3.66 per cent. Generally, contracted pelves occurred in thirty cases, once in forty cases, or 2.50 per cent. Flattened pelves occurred in fourteen cases, once in 85.71 cases, or 1.16 per cent.

3. Twenty, or 45.45 per cent., of our cases of pelvic contraction were among American-born women, and deformity occurred once in 24.95 of these cases, or in 4 per cent.

4. Three, or 6.81 per cent., of the contracted pelves were among black women, and deformity occurred once in ten of these cases, or in 10 per cent.

5. Our material gives a frequency of contracted pelves (1,200 cases, 3.66 per cent.) midway between the conclusions of Williams (Baltimore, 1,000 cases, 13.1 per cent.); Crossen (St. Louis, 800 cases, 7 per cent.); Reynolds (Boston, 2,127 cases, 1.13 per cent.) and Flint (New York, 10,223 cases, 1.42 per cent.).

6. Our statistics, 3.66 per cent. of contractions in 1,200 cases, differ from those of England (F. Barnes of London, 38,065 cases, 0.5 per cent.); of France, 5 to 21.11 per cent.; Germany, 9 to 9 per cent.; Switzerland, 8 to 16 per cent.; Austria-Hungary,

2.44 to 7.8 per cent.; Russia, 1.2 to 5.1 per cent.; Italy, 18.13 per cent.; Holland, 3.51 per cent.

7. Special or irregular forms of pelvic contraction as osteomalacia, obliquely contracted coxalgic, double coxalgic, spondylolisthetic and kyphotic, fractured pelvis, are infrequent in this country.

8. The generally-contracted pelvis is the most frequent deformity met with in New York. I found twice as many generally contracted as flattened pelves in my material (30.14). Williams found practically the same condition in Baltimore (79.45).

9. Records kept of private and consultation cases in New York over a period of ten years show a somewhat higher percentage than the results obtained from the 1,200 hospital cases, namely about 5 per cent. for all deformities; the generally-contracted pelvis being twice as frequent as the flattened.

The Tongue as a Diagnostic Factor in Disease.—L. G. LeBeuf says that the tongue should be examined for the following physical signs: (1) Movement or mobility: in all adynamic fevers of a low type, in nervous diseases or conditions following nervous debility the tongue is protruded very slowly or with a certain tremulousness; (2) Volume or thickness of shape, with indentation of teeth or not, conditions of the digestive system, conditions generated from the hygiene of the organ itself or from direct structural causes, as well as many other conditions, may be ascertained by observation of these points; (3) Dryness to the touch gives information in the exanthematous diseases, in affections of the gastrointestinal tract and in typhoid fever as to the exact condition of the glandular system; (4) The color of the tongue varies in jaundice, stomatitis, scarlatina, and measles. It is also very red in the other exanthemata, but pale and whitish whenever the blood is watery and deficient in red blood corpuscles. It is livid and blue when there is a mechanical obstruction to the flow of venous blood, or where there is improper pulmonary circulation; (5) The character and appearance of the coating is of a special kind in different affections. The author calls attention to the starvation or exhaustion tongue, characterized by a peculiar white, dry coating, cracked alongside of the median raphe, and having distinct rows of raised epithelium on both sides of the raphe.—*New Orleans Medical and Surgical Journal.*

SOME CHRONIC PATHOLOGICAL PROCESSES SEATED IN THE DEEP URETHRAL REGION INVOLVING THE MALE SEXUAL FUNCTION AND NERVOUS SYSTEM.

By J. M. THOMPSON, A.B., M.D.,
BOSTON, MASS.

It is only within the past decade that writers on genitourinary diseases have elicited any appreciable interest in or devoted any marked attention to the sexual and nervous phenomena associated with pathological processes seated in the deep male urethra. While the majority are convinced that the prostate gland and vesiculæ seminales are the organs essentially concerned in causing these phenomena, there are a few who still maintain that the prostate is not a contributing factor in the etiology of deranged sexual function. The claim of the latter authors is that affections of the prostate give rise to disturbances rather in connection with urinary drainage, and for the reason that this organ rarely loses its power of muscular contraction. Such a theory appears to be based on the assumption that the prostate gland is a urinary organ to some extent. A glance at its embryology and physiology, however, will show conclusively and beyond a question of doubt that it is not even related to the urinary tract, except by accidental position; on the contrary, it is a very essential factor in the make-up of the male sexual apparatus.

We need no stronger assurances than the theory of evolution that organic growth is not committed to chance or to accident, but that it goes on unceasingly in obedience to Nature's laws and demands. The prostate arises entirely distinct from the other parts of the urinary tract—a striking and most corroborative proof of the evolutionary principle, namely, the need of an organ is the cause of its development—and remains rudimentary until puberty, when, with the testes, it completes the cycle of its growth, and assumes full physiological importance to meet the demands of the sexual apparatus. Until puberty, then, the prostate possesses anatomical significance only. It is plainly evident that its function was intended to subserve the wants, not of the urinary, but of the sexual apparatus, and is threefold, viz., first, to supply a lubricant for the urethra previous to ejaculation; second, to preserve the vitality of the spermatozoa; third, to assist the seminal vesicles in the act of ejaculating the semen.

Like the prostate, the seminal vesicles play no part in the physiology of the animal economy until the sexual function has been firmly established. Until very recently nothing definite was known regarding the function of these bodies, of which our knowledge has been lamentably deficient beyond their anatomical existence. It is now settled beyond a doubt, however, that they share with the prostate and testes in the make-up of the male sexual apparatus. Each vesicle serves as a receptacle for the testicular secretion, and as a laboratory, so to say, in which to add its own product to complete the composition of the semen preparatory to ejaculation, in the performance of which act it assists the prostate. It will be seen, then, that in point of muscular and secretory functions, the prostate and seminal vesicles bear a strikingly close resemblance. The vesicular secretion, while not essential to the fecundating quality of the semen, nourishes and sterilizes it, so to say, by preserving the vitality of the spermatozoa till ejaculation takes place. Since the prostatic secretion precedes the ejaculation of semen, it is reasonable to suppose that the former was not innded to be a constituent of the latter. Inasmuch, too, as spermatozoa die in an acid medium it is necessary that some means should be provided to prevent the urethral walls, so constantly bathed in acid urine, from becoming a menace to the life of the spermatozoa at such times as the seminal fluid is likely to be expelled. This means Nature has provided in the prostatic fluid, the expulsion of which occurs in sufficient time before ejaculation to prepare a safe and clear way for the passage of the semen.

Through the prostate and seminal vesicles it will be seen that a peculiarly intimate relationship exists between the deep urethra and the sexual apparatus. To show that a no less intimate connection obtains between the deep urethra and the general nervous system, it is sufficient to state that the nerve centers which preside over erection and control the secretion of semen, as well as those which govern the action of the vasa deferentia and of the seminal vesicles, are to be sought in the lumbar region of the spinal cord.

When to the above is added the interesting fact that those organs which are the last in order of development are generally the first to be disturbed by disease, surely, it is not to be wondered at that nervous and sexual phenomena should be the inevitable consequence of chronic urethral processes involving the prostate gland or the seminal vesicles.

Conspicuous among those of the old school who devoted attention and study to "neuroses of the genitourinary system in the male" was Professor Ultzmann of Vienna. He pointed out the significance of the gonorrhœal process that, by extension, involves the prostate, thereby producing nervous and sexual phenomena of the most varied and complex character. Ultzmann viewed the subject from the standpoint of the neurorologist, and classified all sexual disturbances as neurotic, ignoring completely pathological and functional causes.

The late Dr. Beard of New York deserves mention in this connection. His untiring devotion for over half a century to the study of that large and perplexing family of functional nervous disorders so prevalent in America, contributed materially to our first knowledge of neurasthenia. His work on sexual neurasthenia, published in 1891, left little to be desired in point of symptomatology; but, as he saw everything from the vantage ground of the neurologist, his etiology is glaringly defective.

During the past few years contributors to genitourinary literature generally recognize the constantly increasing prevalence of impaired sexual function and neurasthenia in connection with certain forms of inflammation of the deep urethra. It is deeply to be regretted, however, that such wide discrepancy of opinion should prevail among them concerning the exact nature and extent of the pathological process.

According to the theory of Finger of Vienna, in those cases of chronic urethritis in which the sexual and nervous spheres are affected, the prostate is necessarily involved. He, therefore, designates them as cases of "chronic prostatic urethritis." Fuller of New York maintains that the seminal vesicles and not the prostate are the seat of the process, and bases his claim on the presence in the expressed product of spermatozoa, which, he says, are not found in the prostatic fluid. He, therefore, favors the title of "chronic seminal vesiculitis."

Finger asserts that in the prostatic form of chronic posterior urethritis a more advanced and serious condition is present, in which the pathological process has extended further and penetrated deeper into the substance of the gland giving rise to a catarrhal condition of the prostatic ducts, of the sinus pocularis and of the ejaculatory ducts, causing reflex excitability.

Those authorities opposed to the views of Fuller, while they do not deny that spermatozoa belong to the semen proper, do not allow that the presence of spermatozoa in the expressed material is sufficient evidence upon which to rule out prostatic involvement. That the fecundating elements of the semen are found in the prostatic product at times, as the result of regurgitation after ejaculation due to rigidity of the walls and to stenosis of the mouths of the ejaculatory ducts, has been demonstrated by finding spermatozoa in the diverticula of the prostate after death.

In the experience of the writer and of the majority of those who have published their results in the management of cases of chronic posterior urethritis affecting the sexual function and nervous system, the prostate has been involved no less frequently than the seminal vesicles. And when one considers that, in order to reach the vesicles, the urethral process must needs pass through the ejaculatory ducts, it is only reasonable to expect extension into the substance of the prostate.

Symptomatology.—The subjective and objective manifestations of this particular phase of deep urethral disease are so numerous and variable that only those will be considered that are characteristic and essential to diagnosis. The patient is likely to have a history of one or more previous attacks of urethritis of long duration, and complicated by extension into the bladder or by epididymitis. Sexual indiscretions are common in some, while unreasonably persistent continence may have been the rule in others. The present history will disclose chronic periodic discharge at the meatus, especially following erections, coitus, defecation, and sexual excitement. The urine is cloudy at times, and in very nervous patients has a milky appearance, especially at the end of micturition. There is more or less discomfort in the region of the perineum in some patients, with difficulty in starting the urine, which comes out feebly, and at times in spurts. Tenesmus of the vesical neck may be present. When the prostate and vesicles are involved, at first, sexual ardor is easily aroused, even by anything the least suggestive. Emissions are premature during coitus and devoid of the normal amount of satisfaction. Pollutions, too, are frequent, and are followed by a feeling of weakness and depression. Later, erections and emissions become less; sexual desire gradually disappears, accompanied by indifference to female society. The external genitals become relaxed, anæmic, shrunken, and cold, while the normal moisture secreted about the corona is absent. Pruritus ani and itching of the scrotum are not uncommon. The symptoms most significant of prostatic and vesicular involvement, however, are prostatorrhœa and spermatorrhœa, which are difficult to differentiate, except by aid of the microscope. The discharge in prostatorrhœa, an excessive or pathological amount of secretion from the prostate, does not contain spermatozoa unless in exceptional instances, where they are few in number; spermatorrhœa will show an abundance of either live or dead spermatozoa. It is possible, however, to find spermatozoa absent when the vasa deferentia are obstructed, as sometimes follows double epididymitis. In this event it will be necessary to allow the secretion to be exposed for several hours, when, if the spermatic crystals peculiar to the vesicular secretion are found, prostatorrhœa can be ruled out. The nervous phenomena are of a subjective type, and vary according to the temperament of the patients, always suggestive of neurasthenia, but not of any particular variety.

Diagnosis.—It can be said at the outset that in no form of urethral disease are mistakes in diagnosis so frequent as in that where the prostate and vesicles are involved, for no other form entails such extreme care and attention to details on the part of the physician. It is needless to say, then, that one should be certain of the exact nature and extent of the pathological process before attempting to administer treatment.

Inasmuch as many patients do not seek the advice of a physician till unmistakable signs of disease appear at the meatus, it is advisable at first to determine if any anterior urethritis exists. This will be demonstrated by the presence of the "good-morning drop," and the meatus will be glued together more or less during the day. Unless the amount of secretion in anterior urethritis is particularly scanty, a drop or more may be squeezed out at any time, while the morning urine—either clear or cloudy—will always contain shreds. The next step is to irrigate the anterior urethra thoroughly with warm water, by passing a soft flexible bougie back to the bulb. The patient then voids a small portion of urine into a glass, which will be either clear or cloudy. If this urine contains shreds (comma or hook-shaped) posterior urethritis is present. The physician should now ascertain whether the posterior process is superficial—purely mucous—or extends into the deeper tissues and involves the prostate or seminal vesicles. One should not be satisfied with the presence of prostatorrhœa, spermatorrhœa, and other signs of deranged sexual function, in reaching a decision, but should proceed at once to massage the prostate and the vesicles separately. Evidence of prostatic inflammation will appear either at the meatus or in the urine voided after massage. If the urine should be voided in three portions, the third will contain whatever is squeezed out by the muscular spasm at the end of micturition. In the same way one may determine the existence of vesicular inflammation. It is a good plan to substantiate one's diagnosis made by massage, through a microscopic examination of the urinary sediments and expressed products. Furthermore, to resort to the microscope, at times during the course of treatment in order to learn what changes are going on, is to be commended as the only reliable means of enabling one to render a prognosis.

The secretion thus obtained from the prostate—known as prostatorrhœa—presents under the microscope numerous pus cells, polygonal and cyndrical epithelia from the excretory ducts, amyloid bodies, and the colorless refracting granules of lecithin, which are smaller than red blood corpuscles; and when the secretion has been exposed for several hours Bottcher's spermatic crystals are found, designated by their peculiar needle or whetstone shape—all either isolated or imbedded in mucus.

When the deep urethral inflammation extends beyond the prostate into the seminal vesicles, the process may be considered somewhat more advanced and extensive. The expulsive power of the vesicular walls becomes affected—in fact, the vesicles, like the prostate, fail to meet the physiological requirements of the sexual apparatus in every particular. The result is that the testicular fluid is not retained properly by the vesicles, and the ejaculation of semen is more or less imperfect and incomplete. In consequence a pathological escape or discharge of semen oftentimes goes on without the knowledge of the patient. This seminal discharge, known as spermatorrhœa, appears at the meatus periodically and in the urine constantly. Under the microscope this will be found to contain spermatozoa, dead or alive, spermatic cells and granules, epithelial and puss cells, singly and in groups, entangled in mucus.

Treatment.—In the management of this deep urethral process the physician should be possessed of patience, perseverance, and a thorough knowledge of the therapeutics of urethral disease, born of wide practical experience. He should understand the mechanism and physiology of each and every part of the sexual apparatus, and have a clear conception of the importance that normal sexual vigor bears to the well-being of society and of the individual. He should remember, too, that neurasthenia and deranged sexual function are likely to render the patient skeptical, suspicious, and fickle of disposition. Therefore, it behooves the physician at the outset to gain the confidence of the patient, who, in turn, should abide by the letter and spirit of all therapeutic requirements; otherwise success is uncertain.

For the removal of the pathological process seated in the urethra and in the prostate gland and seminal vesicles, it will be necessary to employ certain remedial measures, which have been found by experience to prove efficacious. They may be divided conveniently into rectal (*a*), urethral (*b*), and constitutional (*c*).

(*a*). *Rectal.* This consists chiefly of massage, or stripping, of the vesiculæ seminales, of the prostate gland and of the ducts, and is employed at intervals of from three to seven days and more. In some cases, such as those which are not due to the extension of an acute infectious urethritis, but result from sexual indiscretions and unnatural practices, massage oftentimes appears to be sufficient in itself to remove the localized inflammation. Some writers recommend having the patient in a recumbent position, but this will not prove so convenient and satisfactory as the so-called "leap-frog" position, which requires the patient to stand, his feet about twelve inches apart, and body bent forward about 45° beyond the vertical line, resting the hands of his extended arms on the back of a chair. The legs should be straight, the body relaxed and at ease. The patient should be told to breath naturally and to avoid straining—in short, not to antagonize the operator in any way. The rectum should be relieved of fecal matter and the bladder moderately full of urine, a small portion of which should be voided before massage is employed to serve as a specimen for comparison with that which contains the expressed products. The operator is seated behind the patient, and near enough to pass comfortably the index finger into the rectum; the arm not in use may be passed about the patient's body to exert counter-pressure with the hand on the abdominal viscera in front of the vesicle that is being emptied. At first, and while the vesicles and prostrate are tender, the massage should be gentle and slight, the motion of the fingers being downward and inward toward the ejaculatory ducts, at an angle with the middle lobe of the prostrate of about 45°. In massaging the prostate the finger should move upward and inward toward the median line and in a semicircular direction, always bearing in mind the direction of the mouths of the ducts, through which the inflammatory product is to be expressed. Inasmuch as some of this product escapes forward into the anterior urethra, the patient should hold a glass receptacle near the meatus to catch the overflow. Experience will prove the only guide in determining the amount of massage indicated at each visit. Too little is always preferable to too much. In very nervous patients and those predisposed to hemorrhoids, extreme caution and discretion should be used in order to prevent the patient from abandoning treatment. It is invariably true, however, that patients who find massage disagreeable, or even painful, at first, as soon as they observe the expressed product diminish and the urine clear up, become very hopeful and improve rapidly till fully recovered.

(*b*). *Urethral.*—When the prostatic and vesicular products have been reduced to *nil* by the massage, treatment should be directed to the original urethritis, for the removal of which copious irrigation is no doubt the remedy *sine qua non.* Among the different agents employed for irrigating solutions, protargol appears to be the one most widely recommended, and should be preferred to the other silver salts and to permanganate of potash, as it can be prepared to meet all possible indications. Beginning with a solution of 1-1,000, which may be increased in accordance with the demands, protargol irrigations should be given every two or three days through a posterior recurrent irrigator, or through a soft flexible bougie, which allows the fluid to go into the bladder, to be siphoned out, or voided by the patient. It is a good plan to balloon the urethra occasionally as the flow returns, to make sure that the follicles and deeper tissues are reached.

Although some cases may appear to be quite cured after a course of stripping, it is not wise nor judicious to discharge the patient. A pathological process that has been present for months, not only in the mucous membrane, but also in the subepithelial tissues of the urethra, is not likely to disappear of its own accord. On the contrary, it must be removed, and this can be done best by copious irrigations with an agent that will penetrate the deeper urethral tissues, without provoking irritation and, at the same time, will exert proper antiparasitic, antigonorrhœic, and astringent power. In protargol, mentioned above, it is convenient for the physician to know that we find the desired combination of properties, in virtue of which it is *facile princeps* among the irrigating agents employed in chronic urethral inflammations. This salt is a chemical compound of silver and a proteid, in such proportions that aqueous solutions of it penetrate the tissues unchanged, without undergoing precipitation, even when left in contact for any length of time; neither do they form compounds with the normal tissue fluids. Besides, protargol destroys the gonococcus with absolute certainty, and the strongest solutions indicated do not irritate.

Some cases, especially those in which there has been marked atony and sluggish circulation, will be much benefited by cold steel sounds following, or alternating with irrigation. A sound of as large a size as will pass the meatus comfortably should be introduced and retained for several minutes about every five days. No better means can be employed to tone up the urethral mucous membrane and sexual function; moreover, the effect produced is likely to be a lasting one. Of late some physicians appear to prefer urethral dilators to steel sounds, the majority favoring the instruments devised by Kollman. In cases in which the meatus is particularly narrow and dilatation with irrigation is indicated, these instruments are useful, as they can be employed in the posterior as well as in the anterior urethra, and have a recurrent irrigator attached to them. When the need for dilatation is limited to certain well-defined areas in the urethra, Kollman's dilator is a convenient and satisfactory instrument, and oftentimes to be preferred. Patches of granulation tissue and strictures that give rise to a catarrhal secretion can be combated successfully with the Kollman instrument, but where a thorough dilatation of the whole urethral canal is called for, as in cases of impeded circulation and deranged sexual function, nothing takes the place of cold steel sounds.

A meatus that is noticeably small in relation to the diameter of the urethra, whether congenital or the result of previous history of localized inflammation (chancre, gonorrhœa, etc.), is an indisputable source of reflex irritation at the vesical neck as well as in the prostate and seminal vesicles. In stubborn cases of deep urethral inflammation and deranged sexual function a moderate meatotomy (28° to 32° F.) oftentimes proves to be the one remedial measure necessary to bring about the desired effect.

(*c*) *Constitutional*—Under this head are included all such therapeutic measures as are not local, or mentioned above under rectal (*a*) and urethral (*b*). It is to be suggested, however, that constitutional treatment should not be used as a routine practice essential in all cases, but rather to meet special and urgent demands. Medicinal remedies should be tabooed, except as a last and only resort to supply temporary and otherwise irremediable wants. Every patient must be impressed and in hearty accord with the truth of the old adage "know thyself" in its widest application, and should make the first law to himself that of self-preservation, which admits of no artificial support or stimulation. Whatever proves to be a nervous or sexual excitant should be avoided. Temperance, regularity, and discretion should guide one's mode of life and habits. Diet should be plain, abundant, and nutritious. Exercise, fresh air, sunshine, and bathing should receive the patient's attention daily; but horseback, bicycle riding, and such forms of exercise and recreation as produce exhaustion or local irritation are to be eschewed. The sexual power of the individual serves as an infallible guide, or barometer, of his physical condition and bodily well-being. A rise or fall in the latter effects a corresponding rise or fall in the former.

Case I.—Chronic Vesicoprostatic Urethritis, with Impaired Sexual Function and Derangement of the Nervous System. Etiology, gonorrhœa and persistent withdrawal during coitus for several years. A strong, vigorous, well-preserved man, aged forty-four years, nearly six feet in height, and weighing about 180 pounds; married eighteen years; presents a history of acute gonorrhœa contracted two years ago and lasting several weeks. Habits, temperate and discreet in every particular, beyond an indulgence in withdrawal during coitus for the past few years. Since his attack of gonorrhœa he has noticed a gradual decline in sexual vigor. For several months past he experienced, at times, discomfort in the region of the perineum and bladder, with a feeling of relaxation and weight in the scrotum. Occasionally there was slight tenesmus after voiding urine, and some difficulty in starting the flow. Of late, too, he became indifferent to coitus and has complained of a languid, tired feeling, with pain in the lumbar region. Despite sexual intercourse, he suffered from occasional pollutions, which he thought caused him to feel "dopey" the following day. He realized no disturbance of the nervous system till about a year ago, when he began to have restless nights, which developed later into insomnia. His attention was called to a slight discharge at the meatus for the first time on July 13, 1901, twenty-four hours following coitus. This discharge persisted without marked increase in amount or consistency, unaccompanied by pain, scalding, or other symptoms, till July 19, when, fearing he had contracted gonorrhœa, he consulted the writer.

As the patient was unable to avoid urine at the time of his first visit, and was not disposed to submit to rectal examination, a culture of the discharge was taken and diagnosis deferred till his next visit. In the meantime, however, he was ordered to take a tenminim capsule of sandalwood oil after each meal and at bedtime, with 7½ grains of urotropin morning and evening, and to avoid whatever was likely to irritate in any way the urethral mucous membrane. On July 22 the discharge was reduced to the "good-morning drop," and, as no gonococci were found to be present, a rectal examination was made for evidences of deep urethral disease. The vesicles and prostate were found to be enlarged, indurated, and extremely tender to touch. Massage proved almost unbearable, and the urine voided before and after was cloudy and contained an abundance of shreds (Fuerbringer's hooks) and clumps. The expressed product collected at the meatus during massage and the urinary sediment were submitted to a microscopic examination, which disclosed both prostatic and vesicular elements, with the results as illustrated in diagram 1.

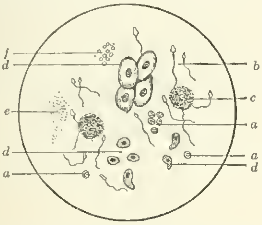

DIAGRAM I.

CASE I.—(*a*) pus isolated and in groups; (*b*) spermatozoa; (*c*) spermatic cell; (*d*) round, caudate, cylindrical, pavement epithelium; (*e*) spermatic granules; (*f*) lecithin granules (author's case)

In this case a thorough massage of the seminal vesicles and of the prostate gland was administered every five days. At first about forty minims of a thin, milky, opaque material, was expressed through the meatus, while a much larger quantity escaped backward and was voided in the urine. Under continuous regular treatment there was a steady and progressive diminution in the amount of the vesicular and prostatic products, so that massage was no longer deemed necessary after August 30, on which date the urine was voided clear and free from shreds. It should be remembered that in patients in whom sexual function is perfectly normal the appearance of a drop or two at the meatus and a slight murkiness in the urine occasionally after massage, is not inconsistent with normal sexual vigor, or with otherwise good physical well-being.

On September 1 the chronic process seated in the urethral mucous membrane proper and in the underlying layers was treated by irrigation of a quart of protargol solution, 1–1,000 in strength, by means of a soft flexible bougie, No. 15 F., passed at first just beyond the compressor urethræ, thus irrigating the deep urethra in the direction of the bladder. As soon as the patient experienced a feeling of distention or discomfort, the bougie was drawn forward gently till it reached the bulb in front of the compressor muscle, when the irrigating fluid was seen regurgitating at the meatus. With the bougie held in this position, the distended anterior urethra was irrigated till all the protargol solution had escaped from the reservoir, which generally hung about two feet above the level of the penis, and in such a position as to be easily raised or lowered according to the greater or lesser amount of pressure desired. Irrigation by this method was continued every three days till September 21, after which cold steel sounds from No. 22 F. to No. 28 F., were passed about twice a week to October 6, when the patient was discharged cured. He reports by letter on November 1 that he is perfectly well and as vigorous sexually as he has reason to expect.

Case II. Chronic Vesicoprostatic Urethritis, with Marked Sexual and Nervous Derangement. Etiology, gonorrhœa, combined with sexual irregularities and indiscretions for several years. A medium-sized, feeble, anæmic-looking man, aged thirty years; weight, 140 pounds; single, was considered delicate during boyhood and youth, while the past ten years have found him in possession of good general health. His habits have been exemplary, even to abstaining from alcohol and tobacco, and coitus was indulged in only occasionally to a moderate extent. He admits, however, that for many years, and at times, frequently, he suffered from ungratified sexual desire, but he never observed anything wrong with his sexual organs previous to December, 1897, when he contracted gonorrhœa, which required constant attention for six months. While he recalls no extension into the deep urethra, bladder, epididymis, or other parts, he is assured the attack was an exceptionally severe one and reduced his general health materially; in fact, ever since he has had more or less discomfort in the urogenital region, with periodic outbreaks of discharge at the meatus. As often as he sought and followed the advice of a physician, so often was he informed that he had a "new dose." On one occasion a diagnosis of stricture was made, and by the untimely or unskilful introduction of sounds, his condition became aggravated, whereupon he resolved to become his own physician, for a time, at least. About six months ago pollutions began to occur frequently, and loss of weight and strength became gradually and progressively more marked. He became languid, morose, and depressed in spirits, preferring solitude and quiet to the accustomed companionship of friends. He lost ambition, and, though a laborer and dependent solely upon his own efforts to earn a livelihood, occasionally would shirk duty which he was physically able, but mentally unwilling, to perform. It is scarcely necessary to add that all sexual desire had now become a thing of the past. Latterly, however, his discharge appeared to diminish and pollutions ceased altogether. He noticed at times a glairy, gelatinous, starch-like material oozing from the meatus after straining at stool. His nervous system was sensitive, and he was easily provoked and frustrated, while his arms and legs were tremulous and unsteady, especially in the morning. With renewed hope, and possessed of a determination to get well, he consulted three physicians on June 16, 1901, including the writer, under whose advice and treatment he decided to place himelf. As the case suggested deep urethral disease, no time was lost in making a digital examination per rectum, including massage of the seminal vesicles and of the prostate. Before and after this procedure the patient was requested to void urine into two separate portions, the sediment of which was submitted to a careful microscopic test. The right seminal vesicle and corresponding lobe of the prostate were found to be considerably enlarged, slightly indurated, but not tender, while the left vesicle and left lateral lobe of the prostate were nearly normal. Massage caused neither pain nor discomfort, owing, perhaps, to the relaxed condition of the parts. The expressed product was abundant, thick, and tenacious, and adhered to the urethral walls to such an extent that it was necessary to force it into a receptacle for examination. The urine voided before massage was clear, but contained some flakey material, while the urine in the second glass, after massage, was slightly murky, and contained a much larger amount of the same material, together with shreds and granular matter. Microscopic examination revealed prostatic and vesicular products, the composition of which is illustrated in diagram II.

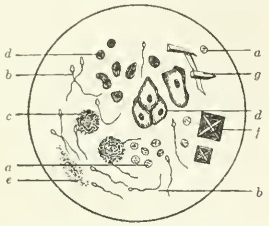

DIAGRAM II.

Case II.—(*a*) pus isolated and in groups; (*b*) spermatozoa; (*c*) spermatic cell; (*d*) pavement, round, caudate, cylindrical epithelium; (*e*) spermatic granules; (*f*) calcic oxalate; (*g*) Böttscher's crystals formed in specimen 24 hours after voiding (author's case).

As in Case I massage was employed every five days from June 16 to July 21, when copious irrigations of protargol, 1–1,000, were substituted and continued every three days to September 21. The strength of the solution was then increased to 1–800, which met the indications perfectly. On October 18 the protargol irrigations were discontinued, inasmuch as the expressed vesicular and prostatic products were reduced to *nil*, and the urine was clear and quite free from all pathological elements. Cold steel sounds, 23F. to 27F., were then introduced and retained for several minutes twice a week until November 1.

In additon, this patient received constitutional treatment in the form of iron, quinine, and strychnine after meals, and a cold plunge bath on rising each morning. When discharged he admitted frankly that he was cured, having gained under the treatment weight, strength, and sexual vigor. He was advised, however, to continue the general tonic measures, and to report occasionally for examination.

Case III.—Chronic Seminal Vesiculitis, with Deranged Sexual Function and Neurasthenia. Etiology: Excessive indulgence in coitus, though not frequent, was continued at times for nineteen years, together with prolonged, ungratified sexual ardor during the same period. A medium-sized man, dark complexion, aged thirty-nine years, weighing 135 pounds, single; occupation, healthful; habits, abstemious; past history, excellent, with no venereal disease; was never cognizant of any derangement of the sexual function previous to July, 1901. At that time his attention was aroused by a discharge of blood from the urethra following coitus, but unaccompanied by other symptoms. A month later he observed considerable blood mixed with the seminal product of a nocturnal emission, after which micturition became more frequent and urgent, with tenesmus at the end. The scrotal contents above the left testicle felt hot, swollen, and irritable, and his discomfort increased on standing. There was no discharge at the meatus, and no abnormal emissions. Fearful of the outcome, he now sought the advice of a physician, who, assuring him he was all right, prescribed a sexual stimulant internally three times a day and more intercourse. He failed to show improvement under this treatment and consulted the writer for the first time on August 19, 1901. In the face of such an unusual history the patient was requested to void into a glass a small portion of urine. On inspection this was distinctly opaque and of a dark reddish hue, and when allowed to settle was seen to contain flakes and clumps of thick, starchy, jelly-like material, the greater part of which resembled clotted blood. The bottom of the glass was literally covered with a fine granular deposit, which, in color and appearance, was not unlike cayenne pepper. Digital exploration per rectum proved almost unbearable. Both seminal vesicles were enlarged, exquisitely tender to the touch, and somewhat indurated. As it seemed inadvisable to perform massage, diagnosis was made from the microscopic manifestations revealed in the urinary sediment (a large amount of which was present in the second portion of urine, which was cloudy and shreddy), and illustrated in diagram III.

As the patient appeared to be in a state of high nervous tension and considerably alarmed, a somewhat expectant plan of therapy was pursued for a few days at first, consisting of rest, liquid diet, abstinence from sexual and nervous stimulants and excitants, and hot sitz-baths night and morning. Seven and one-half grains of urotropin twice a day and tincture hyoscyamus and fluid extract pichi, of each ten drops, every four hours, were administered. In six days he was much improved and at ease; the reddish hue had disappeared from the urine, and as he was able to tolerate a digital examination per rectum without discomfort, massage of the vesicles was begun. This treatment was carried out every seven days till October 31, when the vesicles were reduced to their normal size, and no pathological deposit was discernible in the urine or at the meatus; furthermore, there was an entire absence of all sexual and nervous phenomena. The patient reported a gain of nine pounds in weight, and was assured that his health in every particular was better than it had been for several years.

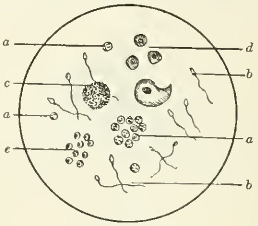

DIAGRAM III.

Case III.—(*a*) pus isolated and in groups; (*b*) spermatozoa; (*c*) spermatic cell; (*d*) round, caudate epithelium; (*e*) blood.

Remarks.—Whether the pathological process is limited to the vesicles or involves the prostate, the plan of therapy is practically the same, except that in cases of simple vesiculitis, massage alone will suffice oftentimes to meet all indications. It is good surgery, however, to irrigate the urethra two or three times, at least, even in the mildest cases.

As patients, while under massage, make a steady improvement almost invariably, evidence of which is seen in the diminished amount of the expressed product and in the clearing up of the urine, it will produce both a wholesome and a reassuring impression on the patient to keep him informed of the fact. The confidence and enthusiasm of the sceptical may be restored by permitting them to observe the spermatozoa under the microscope occasionally.

In addition to possessing the knowledge that is essential to a proper application of the therapeutic measures required, the physician should see to it that each and every patient learns to know what may be termed (if it be allowed the writer to coin a phrase) the limit of his own sexul power or vigor; otherwise, sexual impairment is likely to prove the forerunner of sexual impotence.

It is to be hoped that in the not distant future the pathological process discussed above will be classified under some appropriate and universally accepted title, and be relegated to its one and only rightful abode in the domain of genitourinary disease. The writer reports all cases of deep urethral disease that effect the sexual function and nervous sphere under the general head of chronic sexual neurasthenic urethritis, subdividing them under such titles as are used in the nomenclature adopted above.

THE MYSTERIES OF LIFE AND MIND.

By JOHN P. HUBER, A.M., M D.,
ASSISTANT TO THE CHAIR OF PRACTICE, UNIVERSITY-BELLEVUE MEDICAL COLLEGE.

I HAVE read with much interest some literature concerning researches which have been made and are being elaborated by Dr. Jacques Loeb and his colleague, Dr. A. P. Matthews, both professors in the Chicago University. Loeb has produced parthenogenesis, and has demonstrated, so he considers, the identity of vitality and electricity; and he submits that his findings hold out the possibility of arresting death and prolonging life. The elucidation of such propositions as these has from time immemorial been the aspiration of men given to speculation upon the universal mysteries. But it would seem probable that never before have such investigations taken so scientific a trend as in this work of Loeb's.

Matthew's, basing his investigations in large measure upon the findings of Loeb, considers that he has revealed the secret of the nerves, has explained the action of anæsthetics, and has come to some real and definite comprehension of the heretofore inexplicable nature of mind. If his deductions are well founded, we may expect the birth of a new psychology and of a new pharmacology. Therapeutics, too, will have to be studied from new view-points. Possibly the way in which drugs act, of which there is at present so little scientific knowledge, the mode of action in serumtherapy, the effect which toxins and antitoxins have upon the tissues, and similar phenomena, may all receive satisfactory elucidation.

The following paper is purely in the nature of an abstract. I first notice Loeb's work; and I devote a second section to the work of Matthews:

Loeb came to believe that the forces which control living things are identical with those which we know of in the inanimate world; his researches assail a number of long-established positions; *e. g.* the origin of all instincts. A moth flies straight for a flame; birds drawn by the glare to strike against heavy light-house panes are in the morning found dead and scattered about; a flower turns its petals to the light. To the birds we ascribe intelligence; to the flower the attraction of light. Yet it seems as if the same forces ruled over both. The caterpillar climbs to the end of a branch for the fresh bud upon which it feeds. When it is satiated it climbs down again. A fly will lay its eggs in meat, whereon its larvæ may feed, but not on fat. It seems as if some dim intelligence were at work. But Loeb offers a much simpler explanation of how all these, and countless like instances of adaptation of means to an end, come about. We need only assume that the light sets up certain chemical reactions which cause the animal to move, just as it sets up a reaction in a photographic plate, or explodes a mixture of hydrogen and chloride gas; there is "merely a working of positive or negative heliotropism, an attraction or repulsion by the light." Caterpillars will follow the light so long as they are hungry; if they find no food they will keep climbing, conceivably until they die; when they are cold they will not move; in the warm spring sun, they begin to crawl upward; they will do this anywhere and on any substance; when they come in contact with food, they will eat; on being filled, the effect of the light seems just reversed—they will crawl away from it. Certain chemical stimuli from meat (which are lacking in fat) cause a fly to lay its eggs. These stimuli can be produced artificially. There has been simply "chemotactism," a chemical reaction between the sense organs of the fly and the meat. So through many experiments. More curious still is the effect of mere contact. A starfish, turned over, quickly rights itself. This seems an intelligent act; however, suspended in water, and with bits of cork attached to its arms, it keeps turning over and over, with no seeming preference for which side is up. If a piece of wood or stone be offered to which it may cling, no matter in what position, it seems content. Unless its feet have something solid to cling to, the nerves are apparently stimulated; hence the turning motions. Contact brings the animal to rest; this is "stereotropism."

The morphologist declares that the appearance and structure of an animal result from complex arrangements in the germ from whence it springs; but Loeb considers that these can be altered at pleasure, even in the lower forms, by the same simple reactions of light and heat. He cut a cube from the body of a hydroid, a plant-like animal; no matter which side was uppermost, from the top grew the tentacles forming the head, from underneath the roots; this being inverted, from beside the upturned roots came a head, from beside the deposed head a growth of roots. Upon incision in the body of the cerianthus, there promptly came a new mouth, with its ring of tentacles, for seizing food. Mere contact with a solid substance would turn one organ into another. Organs were grown in most absurd places, others were transplanted. Thus by many experiments Loeb showed that there is no complex structure in the germ cells from which these lower animals spring, but that their varying forms are simply a reaction between a specific kind of protoplasm and the physical forces of light, heat, contact, and chemism, which mold it this way or that.

Developments in chemistry suggested to Loeb experiments upon the effect of various chemical stimuli. He took up the well-known problem of the rhythmical contractions of the jelly-fish; if its upper part be cut away, these contractions stop; when

Loeb placed the beheaded animal in a solution of common salt, the movements began again; a trace of potassium or calcium added, they stopped again. Loeb found that this, which was true of the lowly jellyfish, was equally true of the rhythmical beat of the heart. An excised heart could be kept beating for hours, stopped, started, quickened, or slowed, simply by changing slightly the chemical character of the solution in which it was placed.

The beat of the heart, then, is not due to a mysterious influence of the still more mysterious nerves; it comes from the presence or absence of certain salts. The new chemistry helped to show Loeb how these may act. A lump of common salt dissolved in a vessel of water makes the water a conductor of electricity; two ends of a copper wire dipped therein start an electric current; a lump of sugar has no such effect. This remained a problem of chemical philosophy until Arrhenius demonstrated that the molecules of the salts and acids are torn apart when they are dissolved, and apparently with tremendous force. The effect in dissolving the salts is an enormous electrical discharge on the individual atoms; in the tearing apart one set is charged positively, the other negatively; in the case of common salt the metal atoms (of sodium) take the positive charge, the chlorine atoms the negative; these electrically-charged atoms, long before their nature was understood, Faraday named *ions*. As Arrhenius stated: "It is the ions which act." This heritage of science enabled Loeb to make—so it seems—a tremendous discovery. That the ultimate cause of muscular action, and probably of all life processes, is electricity; it is the ions which may cause the heart or a muscle to contract; the negative charges start them—the positive charges stop them.

Loeb proceeded now *to manufacture living beings*. The beginning of life, the process of fertilization, has always been the burning question of biology. From countless myriads of eggs laid by the female organism and the equal hordes of the sperm cells, a single egg and a single sperm unite to form the single microscopic cell from which all forms of animal life originate; unfertilized by the male cells, the eggs quickly degenerate and die. All the problems of life, growth, heredity too, lie buried, then, within this microscopic cell; the sperm and the egg must be the carriers of all that the being transmits to its descendants; exterior forces play here only a minor rôle: such, heretofore has been the biological tenet. But Loeb's researches, on the other hand, tend to show that there is no such transmission; for he has succeeded in producing growth without sperm. He took the sea-urchin's eggs from the ovary, before there could be the slightest possibility of contact with sperm cells and placed them in the ordinary sea-water in which these animals live; a solution of chloride of magnesium caused them to develop to the same stage as they do normally in an aquarium. Thus did he unquestionably produce artificial parthenogenesis. This demonstrated the fact which Loeb came upon that the peculiar actions of the protoplasm are influenced largely by the ions contained in the solutions which surround the cells; by changing the relative proportions of the ions the physiological properties of the protoplasms are changed; thus it is possible to impart to a tissue properties not ordinarily possessed by it.

There is a common chain that links all these reactions—the heart which may be started or stopped with a pinch of this salt or that, the muscles which may be made to beat like a heart, the egg which may be vivified by chemical means. When they come to combine with other atoms, some of the atoms seem, so to speak, to have but a single arm with which to take hold, while others have two, or three, or four, or even five. When wood "burns" the four-armed atom of carbon can seize and hold two of the two-handed oxygen atoms, while in the molecule of water the two-handed oxygen atom will bind two of the single-handed hydrogen atoms, and so on; this is the "valency" of the chemist. Faraday saw that each "valency," each arm, could carry a certain amount of electricity; that was its capacity, and the electrically-charged atoms are therefore not alike; the two-armed atoms carry two charges, the three-armed three charges, and so on: it may be, then, that chemistry, like light, will have to be annexed to the domain of electricity. Loeb has done much to fix this belief; he has found that a pure solution of common salt will not keep the heart or the muscle of the jelly-fish going; a little calcium added sets things right, though too much will act like a poison. Some of the ions, then, are toxic; some are antitoxins. Loeb surmises that this may be true of all poisons—that their actions results from the positive or negative charge of electricity they bear.

Loeb believes that the chief rôle of food is not, as is generally held, to be digested and "burned" in the muscles and organs, but to supply ions; the heat developed is a by-product; the chief action is the production of electricity; the body is in some sort a dynamo; food is of value according to the amount and kind of electricity it affords.

That will o' the wisp, the possibility of prolonging life, naturally occurs to one. From Loeb's work in parthenogenesis it seemed to him that there were two distinct processes going on. "Death and disintegration are not a mere breaking down, a going to pieces, but a specific process that is checked by the life process. Possibly such action may be checked chemically as well. Loeb, by placing the unfertilized eggs in a week solution of potassium cyanide, kept them alive for seven days; 'if seven days, then it is a mere matter of experiment to produce a condition of equlibrium which will endure indefinitely. It seems paradoxical that life may be thus maintained by a powerful poison; but if we conceive of a specific mortal process which may be held in check, and regard the potassium cyanide as substituting a condition of suspended action, the matter seems clear.'"

When Loeb had shown that the muscles might be made to beat or stop under the influence of certain ions, it was but a step to suppose that these same ions might have an equal effect on the tissues of the nerves; Matthews took this step. Much material was already on hand for him; fifty years ago Graham distinguished between substances which crystallize when they solidify and those which do not; the latter he called the colloids, the glue-like substances, as a hen's egg or gelatin, or, speaking broadly, the human body, which is about 75 per cent. water, the rest being jelly and bones. The nerves and the brain cells are 80 or 85 per cent. water. Hardy demonstrated that the colloid particles bear an electrical charge, that these complex molecules act just like a simple ion; further, that the colloids carry positive electricity, and are precipitated by the negative kinds of ions. Then others showed that the anæsthetics—chloroform, ether, and the like—dissolve fats; they deaden, stop sensation—that is, retard the progress of the nerve impulse. The nerves are simply highly phosphorized fats in a weak salt solution. The quick mind of Matthews bridged over from one to the other of these striking facts. Here must be the proces by which a nerve loses its ability to be excited; the thinner the solution in the nerve, the less easily it conducts; the process of stimulation must be just the opposite; a nerve conducts better, is more easily stimulated the nearer it approaches a state of jelly; this would be brought about by precipitation of the colloid substances; and if the latter are positively charged, as Hardy showed, then it would be a negative current, which would effect the precipitation, and hence a negative current that produces a stimulation of a nerve. So Matthews found that a stimulation of a nerve from an electric current always proceeds from the negative pole, the cathode. The muscles of a frog, to which the motor nerve was still attached, jerked when bathed in various solutions of salts; the nerve, then, must somehow have effected a release of negative ions at the point where it blended with the muscular tissue. How? If the negative ions be in excess in the solution, and the positive and negative ions in the nerve be just balanced, the effect would be a precipitation of the first layer of colloid particles bearing positive charges, and in contact with the solution; this would release a certain number of negative ions lying next in the nerve sheath, and these, in turn, would precipitate the adjoining colloids; a wave of precipitation would travel thus along the nerve, and at the end would be a set of free negative ions, ready to call the muscle into action; the nerve impulse, then, is a consecutive series of precipitations. All this, with much else, is as yet simply a working hypothesis; but Matthew's investigations, like those of Loeb, promise to be epoch-making; among much else, they bid fair to revolutionize nervous pathology, psychology, pharmacology, and the like.

HYPERTROPHIC RHINITIS AND ITS SEQUELÆ.

SOME SUGGESTIONS ON DIAGNOSIS AND TREATMENT.

By F. M. HAYES, M.D.,
BUFFALO, N. Y.

During twenty years of special medical practice it has been my privilege in treating many hundreds of cases of these two diseases to have exceptional opportunities for the observation and study of their complications.

I have found hypertrophic rhinitis and the usual accompanying nasal growths most troublesome complications, and they often interfere markedly with the successful treatment of asthma and hay fever. There is a tendency on the part of many general practitioners to pass over these cases too lightly. The term chronic nasal catarrh is commonly applied to all inflammatory and degenerative processes in the nasal cavity. It is to avoid the use of this general and unprofessional term and the errors to which it leads that I strongly urge a careful examination before a diagnosis be made. There is usually a pathological condition which is easily recognized. It is as much the duty of the physician to discover the real cause of the catarrhal symptoms of the nose and pharynx as to make a correct diagnosis of inflammatory changes in any other part of the body.

A lady from a neighboring State recently asked me if catarrh could be cured. On my answering her in the affirmative, she said, "My doctor says nothing but a change of climate will cure me." An examination disclosed hypertrophic rhinitis, involving the mucous membrane covering the inferior turbinates on both sides, while one side showed evidence of polypoid degeneration. No climatic change could remove these growths. I sent her to a rhinologist to have the hypertrophies cauterized and the polypoid growths removed. To prescribe a change of climate in that case was at best only temporizing—the operative treatment was necessary to remove the cause.

Such radical measures are by no means necessary in all cases. I recall that of F. S. H., a farmer, forty-four years of age, who consulted me for nasal catarrh. He gave a history of poor digestion, poor appetite, and gradual loss of flesh. His father died of tuberculosis when the patient was a child. There was no obstruction in the nares. I was convinced that the mucous discharge was due to no local condition, but to his generally lowered vitality. The hypophosphites, with small doses of iron, quinine, and strychnine, and daily cool salt sponge baths, completely restored him to health and all evidence of catarrh disappeared. I again aimed to reach the *cause.*

Give the tonic or alterative treatment indicated and direct the use of Dobell's solution, or Seiler's tablets, for a cleansing spray first, if you choose; but do not stop here, and if your patient returns in a few weeks, showing little or no improvement in the catarrhal symptoms, you have not found the *cause* and must now look for pathological conditions in the nasal cavities.

It is possible for every practitioner to intelligently diagnose hypertrophic rhinitis, polyps, or adenoid growths, and definite pathological conditions will be found in the majority of cases presenting themselves for treatment, with the history of nasal stenosis or nasal discharge. Having made your diagnosis, the indications for treatment are plain, and the advice to seek the skill of the rhinologist for removal of the nasal growths will convince the patient that you have found the cause of the trouble. How much better such a course than to prescribe a change of climate without a thorough examination.

It is my custom to get a minute history of each case before making an examination, and it is remarkable what accurate information can be obtained, from a thorough study of the rational symptoms, and how much it aids us in really recognizing what is found on exploring the nasal cavity. A full family history, including the grandparents, should be required in order to trace any inherited predisposition or tendency to morbid changes or neuroses which will have any bearing on the case. You must also learn if any acquired diathetic condition or constitutional dyscrasia exists. It is necessary to obtain a description of the patient's environment, occupation, habits, diet, and his state of digestion and nutrition. It is very important to discover whether impaired health is the cause or the result of nasal changes. All these points should be distinctly brought out by your questions to the patient.

The local symptoms may be those of polyps, or polypoid degeneration, hypertrophy of the mucous membrane, adenoid growths, disease of the antrum, frontal sinuses, or ethmoidal cells. It is impossible to determine from local symptoms alone the pathological condition present, as some of the symptoms are common to two or more different morbid changes, and these changes rarely exist singly in any given case.

Let us now consider in detail the five pathological conditions which may be found in an ordinary case of nasal catarrh.

Nasal polypi are benign neoplasms and of three varieties—mucous, fibrous, and cystic. They are sessile or pedunculated, and are found growing from the mucous membrane covering the posterior portion of the middle or lower turbinated bones. They are usually of a bluish color, soft and gelatinous if of the mucous variety, but hard and firm if fibrous; not usually very sensitive to touch with the probe, but the slightest atmospheric disturbance will excite the characteristic attacks of sneezing. Indeed, frequent attacks of sneezing are suggestive, especially when excited by sudden changes in temperature, dust, odors, or currents of air striking exposed portions of the body, and should lead to suspicion of the presence of polyps. The cavities of the nose and throat give tone and resonance to the voice, and any encroachment on them is soon detected by the diminished vocal quality. The tone becomes dull and flat, and is said to be nasal. There is often a thin, watery discharge from a polyp, which is very annoying, for it is non-irritating, and a slight change of position of the head will precipitate a discharge of this limpid secretion without warning.

Hypertrophic rhinitis causes obstruction to the free passage of air through the nose by thickening and deformities of the turbinates and the septum. Patients complain that they take cold easily, and that, when they lie on one side, the lower nostril closes. The latter symptom occurs in consequence of the blood gravitating to the turbinates, on the lower side, and making them swell. A slight exposure results in occlusion of both nostrils and, as a result, the constant passage of air through the mouth instead of the nose dries the throat and larynx and gives rise to more or less irritation or inflammation of these parts.

Adenoids are usually found in the vault of the pharynx, growing from the pharyngeal tonsil during childhood and early adult life, and often so plug up the posterior nares as to cause mouth breathing. They secrete a thick mucus difficult to dislodge.

Disease of the Antrum or Frontal Sinus.—A purulent discharge, with an offensive odor, may come from ozæna, but in that case the odor is not recognized by the sufferer, owing to the loss of the sense of smell. It may come from caries of the vomer, but its origin is then easily found, for the ulceration of the septum is plainly seen on examination. The odor may arise from carious teeth, but if so, the absence of pus in the nasal discharge and the presence of decayed teeth would indicate its origin. Having eliminated the above causes, you may be pretty sure that the offensive discharge from the nose points to disease of the antrum or frontal sinuses.

Disease of the antrum is unilateral, for seldom are both antral cavities involved at the same time; hence the pus is only observed on one side. The patient discovers that the discharge is worse when lying on the side that favors emptying the affected antral cavity. Neuralgic pain, referred to the malar bone on the affected side, is a common symptom. When the frontal sinuses are the seat of the trouble the presence of pus, with a sense of fulness or frequent frontal headaches, would point to them as the seat of the trouble.

A rhinoscopic examination of the nasal cavity is necessary before our diagnosis is complete. The examiner should sit immediately in front of the patient and facing him. A three-inch forehead-mirror is required, for only reflected light can be used to advantage in this practice. The surgeon should wear the mirror in front of his eye in such a manner as to look through the perforation in the glass and at the same time shade his eyes from the light. Dilate the alæ of the nostrils, so as to admit the most light; place the hand on the head of the patient and tilt it so that the light will illuminate the cavity of the nose. Artificial light should always be used in these examinations. A Mackenzie's condensor, made to fit an Argand gas-burner or that of an ordinary student lamp, is necessary to focus the light so it can be reflected by the head mirror. This light should be at the patient's back, on a level with his head.

If you find a very narrow space between the septum and the middle or inferior turbinated bone, or if at any point you find contact between the vomer and the turbinates, you have a sufficient explanation for the persistent catarrhal symptoms, for even though contact is not actually present, it will take only a slight congestion to bring the mucous surfaces together. When contact exists between two mucous surfaces in the nose, irritation, congestion, swelling, chronic inflammation, and thickening result; therefore, if the septum touches the turbinates at any point, it is necessary to remove the protruding portion. Exostoses may project from the base of the vomer till they touch the inferior turbinates. There may be deflection of the septum to one side, so as to occlude the nostrils, or there may be sufficient hypertrophy of the mucous membrane covering the turbinates to make them impinge on the septum. Each condition must receive the treatment it requires, the bony growth sawed out, the deflected septum straightened, and the hypertrophied membrane cauterized. All obstructions to free passage of air through the nose must be removed.

We have shown the necessity for operative interference when there is stenosis of the nasal passages or contact of the mucous membranes. A further examination may disclose a convex, glistening mass of bluish-gray color growing from the edge of the middle or lower turbinated bone. This is the typical appearance presented by a polyp. It may be so prominent that nothing else can be seen.

Recently, J. C. called at my office. An examination of his nose disclosed an immense polyp projecting from each nostril, so that it could almost be seen by one sitting across the room. The amount of disturbance produced is no indication of the size of the polyp causing the trouble, for in the above case many of the usual symptoms were absent. Often a polypoid degeneration of the mucous membrane, so small as to escape the notice of many an observer, will cause more nervous disturbance than a polyp large enough to entirely occlude the nasal passage.

The glistening surface of the polyp, or polypoid degeneration, is very significant. In order to confirm your diagnosis, and also to give you a clearer view, spray the nose with a 2-per-cent. solution of cocaine, which will contract hypertrophied tissue, but will not affect polyps. If the glistening protuberance is visible after use of the spray, you may be pretty sure it is of a polypoid nature. A polyp reflects the light so well that its glistening surface may be seen when the rest of the posterior portion of the nasal cavity remains in shadow.

A mucous discharge observed on the back of the pharynx requires an examination of the post-nasal space to determine its origin. This is made with the laryngoscopic mirror, and it requires some practice to manipulate the mirror so as not to touch the pharynx and cause nausea. The practitioner should become familiar with the appearance of the post-nasal space in health, so that he may be able to detect the growth of adenoids from the pharyngeal tonsil. Adenoids secrete a stringy mucus, and may be the origin of the discharge observed on the pharynx; if not, the mucus will be observed to flow through the posterior nares from the nasal cavity.

I have already touched on disease of the frontal sinuses and antrum, so will not refer to them here. Having found sufficient cause in the nose for the catarrhal symptoms, send the patient to a skillful operator. So many rhinologists are satisfied if they can remove one polyp or cauterize the part most easily reached, when nothing but thorough treatment will cure. Miss C. showed, by examination, polyps on both sides, and I advised her mother to take her to a rhinologist. The mother said: "Why, we have just consulted a specialist, and he said there was nothing more to do." I inquired what he had done, and found that he had removed some adenoids from the pharyngeal tonsil. I then asked her if he had made an examination of the nose, and she said "No." A few days later the young lady returned with a large-sized homeopathic vial full of polyps that had been removed since her previous call.

The rational symptoms, of hypertrophic rhinitis and polyps, are often sufficiently diagnostic to point to the presence of nasal obstruction or growths before examining the nose, but the constitutional condition of the patient enters so often as a factor in producing the symptoms of chronic nasal catarrh, that only after a thorough exploration of the nasal cavity can a definite diagnosis be made. As general practitioners, we have been in the habit, in all cases of nasal catarrh, of treating any lowered vitality or dyscrasia with the proper tonic and restorative medicines, hoping that this, with antiseptic and cleansing sprays, would accomplish the cure. It is therefore not necessary for me to touch upon the importance of constitutional treatment.

There is, however, a class of cases, neurosal in origin, that prove exceedingly puzzling, and often lead to errors in diagnosis. These cases are termed by Bosworth "vasomotor rhinitis." They give all the symptoms of frequent attacks of acute head colds, or the exacerbations so common in hypertrophic rhinitis.

The frequent attacks of sneezing, followed by swelling of the nasal mucous membrane, with an abundant discharge, point to the existence of polyps and hypertrophy of the mucous membrane. If, during the height of an attack, an examination is made, the appearance seems to confirm the condition indicated by the rational symptoms, but examine the patient again after the attack has subsided, and you will be surprised to observe no evidence of hypertrophy, and will search in vain for polyps or polypoid degeneration. Here, certainly, is not a case for operative treatment, and the sufferer shows no evidence of lowered vitality, but, on the contrary, seems perfectly well between the attacks.

If the vasomotor rhinitis occurs only during the summer season, you give it different names according to the exciting cause, such as rose cold, peach cold, ragweed catarrh, etc. You advise your patient to go to an exempt locality, where his exciting cause cannot be found, and if he stays away from home until frost has killed vegetation, he may pass through the season without a symptom of his trouble, and think he is cured, but if he should fail to leave for his mountain, forest, or seaside resort till after the date for the appearance of his annual catarrh, it visits him punctually, and drives him from his home. If he returns one week before vegetation is killed, his tyrant is awaiting him. Change of climate is only a relief, and after a few years the victim finds his symptoms returning even in so-called exempt regions, and he is obliged to seek a new locality.

Vasomotor rhinitis is frequently most troublesome in the winter season, and is accompanied by an obstinate cough. If the case progresses, the cough is followed by an attack of difficult breathing, and it is often said that the catarrh has brought on asthma. Occasionally neurosal cases are seen where violent attacks of sneezing occur, frequently without regard to season. Although cough or asthmatic symptoms may be absent, the paroxysms of sneezing may be so frequent and violent as to be more or less exhausting and produce constitutional depression. It is, of course, very important, in all these neurosal cases to exclude all reflex causes. Not only should the nasal cavity be explored, but the eyes should be examined, as eye strain may be the cause of motor disturbance along the respiratory tract. In the concluding paragraphs of this paper, I wish to emphasize the fact that neurosal affections of the upper air passages require a constitutional treatment that will eradicate the cause in order to cure the disease. Never be satisfied with the use of relief measures alone.

Diathesis is a predisposition of the body to certain forms of disease, and is usually inherited. This is especially true of chronic neurosal affections, and it is therefore of the utmost importance that this predisposition should be carefully studied and the treatment directed to it. Any remedial measure necessary for the temporary relief of the painful outbreak of the disease should be taken only until relief is obtained, but the constitutional course of medicines should be given continuously. As changes are brought about in the body by the use of a restricted diet, so by feeding the nerve centers daily with alterative medicines we can permanently remove their morbid tendency. Asthma, hay fever, sick headache, and eczema, comprise a class of diseases in which the treatment is usually aimed at relief or suppression of the symptoms instead of at the diathetic condition.

Reliefs wear out, and local treatment often suppresses the manifestation in one direction, only to have it appear in another form in some other part of the body. I knew a rhinologist who cauterized the so-called "sensitive area" in the nose for the cure of hay fever, and the first attack of asthma the patient had ever had appeared before he left the chair of the operator.

Having carefully removed or excluded all local causes and constitutional dyscrasia, the diathetic condition, the neurosal predisposition is seen to be the true cause of the catarrhal symptoms, and this must be eradicated before a cure is complete. Treatment must consist of tonic and alterative medicines, given in such small doses that their use can be continued for months, for the change in the nerve centers which substitutes a healthy action for the morbid tendency is a slow process.

716 MAIN STREET.

Antitoxin Treatment in Diphtheria.—John H. McCollom, from a comparison of the health reports of Boston before and after the introduction of the anti-diphtheritic serum, from a comparison of the health reports of other cities, from a study of hospital reports, from a clinical observation of more than 10,526 cases of diphtheria, concludes as follows: (1) That the ratio of mortality of diphtheria per 10,000 of the living was very high in Boston previous to 1895; (2) That the ratio of mortality per 10,000 has been very materially reduced since the introduction of antitoxin; (3) That the percentage of mortality in the South Department is lower than that of any of the hospitals taken for comparison; (4) That since larger doses of antitoxin have been given the death rate has been materially reduced, this reduction having occurred in the apparently moribund cases; (5) That no injurious effect has followed the use of the serum; (6) That to arrive at the most satisfactory results in the treatment of diphtheria, antitoxin should be given at the earliest possible moment in the course of the disease.—*The Providence Medical Journal.*

THE MOSQUITO ON BOARD OF VESSELS AT QUARANTINED PORTS AS A FACTOR IN THE TRANSMISSION OF YELLOW FEVER.

By EDMOND SOUCHON, M.D.,
NEW ORLEANS. LA.
PRESIDENT OF THE LOUISIANA STATE BOARD OF HEALTH.

It was about fifteen years ago, in 1886, that the importation of fruit from the tropical ports to New Orleans really began. The main regulation was that no vessel should have any communication with the shore. During that time an average of seven vessels a year were engaged in that trade. Each vessel made an average of two trips monthly during the quarantine season—that is, during six months. There were, therefore, eighty-four trips per year, and during the fifteen years 1,260 trips or vessels. During these fifteen years five fruit vessels arrived at the Mississippi River Quarantine Station with yellow fever on board during the quarantine season. They were:

1887—*City of Dallas*, from Belize, July 6........one case
1888—*Foxhall*, from Limon, August 14.........one case
1889—*City of Dallas*, from Livingston, October 1..one case
1897—*Jarl*, from Bocas, October 27, one case at quarantine and two in the city.
1900—*Adler*, from Limon, August 26..........one case

The percentage of vessels with yellow fever on board is about one-third of one per cent.

During the same fifteen years 1,343 vessels plying between New Orleans and the West Indies, Central American and Mexican ports, arrived at the Quarantine Station. The vessels belonged to the Harrison Line and to the Leyland Line of regular steamers, whose agents kindly furnished the figures.

Besides these, it is estimated that about 250 irregular vessels arrived also at the Quarantine Station, making a total of 1,600 vessels in round figures.

The following thirty-four vessels with yellow fever on board arrived at the Mississippi River Quarantine Station:

1886—August, 15, bark *Scotia*, from Colon......one case
1886—September, 24 bark *Montreal*, from Colon.one case
1887—July 12, S. S. *Inventor*, Colon *via* Belize.three cases
1887—October 20, S. S. *Altmore*, Colon.........two cases
1887—October 20, S. S. *Red Sea*, Colon........one case
1888—March 16, S. S. *Historian*, Colon........one case
1888—March 17, S. S. *Elmsfield*, Martinique....two cases
1888—August 11, bark *America*, Havana......one case
1888—August 16, ship *Marcelina Jane*, Havana.one case
1889—April 18, S. S. *Navarro*, Havana........one case
1891—August 10, S. S. *Wm. Cliff*, Progresso and Vera Cruz..........................three cases
1892—June 11, S. S. *Clintonia*, Havana........one case
1892—August 26, S. S. *Denia*, Havana........three cases
1892—August 28, S. S. *Violante*, Havana......one case
1894—August 6, S. S. *Architect*, Vera Cruz and Tampico.............................one case
1894—August 26, S. S. *Vesta*, Vera Cruz and Tampico...........................three cases
1896—March 13, S. S. *California*, Santos *via* Rio one case
1897—December 8, S. S. *Ainsdale*, Kingston (Jamaica)...........................two cases
1898—August 20, S. S. *Tampican*, Vera Cruz, Tampico, Colon......................one case
1898—August 30, S. S. *Highland Prince*, Vera Cruz, Tampico, Colon.................two cases
1898—October 3, S. S. *Wm. Cliff*, Vera Cruz, Tampico, Colon......................one case
1899—May 18, S. S. *Clinton*, Havana..........one case
1899—May 27, S. S. *Navigator*, Colon, Vera Cruz, Tampico............................one case
1899—July 25, S. S. *Traveller*, Colon, Vera Cruz, Tampico............................one case
1899—October 11, S. S. *Whitney*, Havana......one case
1899—October 18, S. S. *Sardinia*, Colon, Vera Cruz, Tampico......................one case
890—July 3, schooner *Bertha Louise*, Vera Cruz and Chilipec........................one case
1890—July 5, S. S. *Hugin*, Vera Cruz and Tampico.................................one case
1890—August 27, S. S. *Orion*, Vera Cruz and Progresso...............................two cases
1890—October 17, S. S. *Electrician*, Colon and Mexican ports......................seven cases
1901—January 25, S. S. *Atlas*, Vera Cruz, Progresso, Tampico.......................two cases
1901—September 13, S. S. *Darien*, Colon *via* Vera Cruz, Progresso and Tampico............four cases
1901—October 2, S. S. *Astronomer*, Colon *via* Vera Cruz, Progresso and Tampico........two cases
1901—October 29, S S. *Traveller*, Colon *via* Vera Cruz, Progresso and Tampico...........four cases

The study of these vessels show that 8 came from Havana, 8 from Colon, 6 from Colon, Vera Cruz and Tampico, 3 from Vera Cruz and Tampico, 2 from Vera Cruz and Progresso, 1 from Colon and Belize, 1 from Vera Cruz and Chilipec (Mexico). Of these, twenty-nine vessels had yellow fever on board during the quarantine season. The percentage of yellow-fever vessels is about 1½ per cent. These vessels took no measures to prevent communication with the shore.

Remarks.—Of course, no measures were taken against mosquitos in any cases. That mosquitos will reach vessels at anchor in bays has been established by a previous communication of the writer in the MEDICAL RECORD of July 5, 1902. Many other proofs will be forthcoming at the end of the quarantine season.

It is remarkable that the vessels which took measures to prevent communication with the shore developed so few cases of yellow fever, five in 1,260, whereas those who took no such measures developed comparatively so many, twenty-nine in 1,600.

This surely shows that the mosquitos aboard had very little to do with the development of yellow fever, and that the cause of the infection was truly ashore. It may be said, with justice, that this was because mosquitos in houses ashore are much more likely to be infected than the mosquitos in the open and aboard vessels. It may be that the mosquitos aboard are different from those ashore. This point is now under study by this Board.

But the believers in fomites may claim with equal justice that the cases became infected because they came in contact ashore with fomites.

It may also be argued that two or three or more of the five cases are truly due to surreptitious violations of the qarantine regulations by which some from the vessel went ashore unknown or unreported. That is what we believe, because if the infections were due to mosquitos on board there would surely have been more than five cases on 1,260 vessels in fifteen years.

It is true that the fruit vessels came from ports that were not all as badly infected as the ports from which the other vessels came, yet two of these infected fruit vessels out of the five came from Limon, which is perennially as much infected as the West Indies and Central American and Mexican ports.

At least one-third (or about 400) of the 1,260 fruit vessels came from Limon, it being the port of a region whose fruits are of a superior quality. The percentage is one-half of one per cent.

Conclusions.—Let all that be as it may, we cannot see, in the light of such cases, how we can modify without risk the quarantine regulations preventing vessels from having communication with the shore in quarantined ports until those ports have permanently and reliably eradicated the yellow fever by destroying the mosquitos and all other possible causes of infection.

Gift of Osborne House.—King Edward has signalized his coronation by the gift to the nation of Osborne House, one of the favorite residences of Queen Victoria. In the letter announcing the gift the King expresses the hope that the palace may be devoted to national purposes and be converted into a convalescent home for officers of the navy and army whose health has been impaired in rendering service to their country.

THE QUESTION OF PROGNOSIS.

EVERY physician who has inadvertently committed himself to a positive opinion regarding the outcome of a case under his care, learns by bitter experience and becoming chagrin how difficult—in fact, impossible—it is to be absolutely sure of his ground. There are in the vast majority of instances so many incidental circumstances to be considered in forming conclusions that he is never safe in trusting to a possible chance. The verdict, whether pro or con, always determined by time, is sure to settle the question for or against him beyond the chance of explanation for his demonstrated mistake. Thus the wise man always qualifies and inserts the "if" in all his prognostications. In this, avoiding conclusions which are obviously beyond his control, he is willing to venture in a purely suggestive way, as to probabilities, rather than actualities. His reasons for such a course are well-founded and beyond the range of ordinary argument.

He is not long in practice before he becomes aware of the fact that the most unexpected things happen; the most trivial diseases in apparently strong patients end disastrously, while the severe ones, generally looked upon as hopeless, recover. Oftentimes also death occurs as suddenly and unexpectedly as with a stroke of lightning from a clear sky. No one of the signs of dissolution are absolute. Even the hippocratic face sometimes survives to smile at the would-be prophet. The old physician who said he never acknowledged that a patient was dying until after he was dead, was certainly cautious enough not to be caught. Even when at his wits ends to account for the result, he found it safer to accept the explanations of the patient's friends than to offer any himself. It was in one way the cultivation of the faculty of never being surprised at anything, but quietly expecting everything. Ordinarily there are difficulties enough in trying to guide the ship without attempting to govern the storm or the fog. The only cheerful thing to say is that the vessel will eventually reach the port if there be no accident—and death is always the accident. We are told by the highest authorities that the sudden deaths give no preliminary sign. Before an attack of apoplexy, the stroke of which is so often given during sleep, the patient often says on retiring, that he never felt in better physical condition. With heart disease, the victim often passes away with an unfinished sentence on his willing lips. Death simply touches the pendulum and he stops ke a clock. The wasting consumptive, wearily awaiting the messenger, asks that his head be raised—and the last gasp is given. The fatal coma of uræmia often comes on as suddenly as the blowing out of a light. So far as human prediction is concerned, the exact time depends upon a mere whim of the wasting destroyer; and yet the physician is expected to explain the when and the how.

In his contemplation of conditions controlling the outcome of disease he must take many-sided views as to correctness of the diagnosis and treatment, the often uncertain action of remedies, the variable vitality of the patient, and reconcile all to the reactionary tendencies of the particular case in hand. While it is always necessary and proper to be optimistic to the patient, it is never safe to say he is absolutely beyond danger. This would obviously apply with more particular force to the patient's friends, who are not supposed to communicate suspicions to the one most particularly interested. "May he die suddenly?" "I hope not, although sudden deaths are not uncommon in this disease."

When we sum up the situation on the question of the always unknown quantity—the vitality of the particular individual—what more can be said and what more can be expected?

THE TRUE PRACTICAL VALUE OF CRYOSCOPY.

WITH all the mass of evidence which has been accumulating since Koranyi in 1893 applied the freezing test to urine with a view of determining the functional condition of the kidney, cryoscopy is still in the experimental stage. Thousands of observations have been made in all parts of the world, and yet, not only the practical application of the freezing test, but the very theory underlying it presents phases that are awaiting solution.

The disadvantage of cryoscopy over other means of laboratory diagnosis is that the freezing-test has been worked out most ingeniously from a series of physical laws and physiological theories which form inseparable links in a chain of reasoning which leads to its practical application to clinical work. A link in this chain broken, and the whole structure so laboriously wrought, threatens to fall.

To any one who has followed the trend of research in cryoscopy, it must be apparent that whilst most of the work that has heretofore appeared has strengthened and enlarged the possibilities of cryoscopy as a means of diagnosis, there has appeared of late a number of researches which show that the theoretical basis of cryoscopy is by no means necessarily correct in all respects, and that it certainly needs most careful revision.

Cryoscopy—the determination of the freezing point of a solution—is, as we know, dependent upon certain physico-chemical laws affecting solutions which were discovered by Raoult (Comptes rendus de l'Academie des Sciences, November, 27, 1882) and Van t'Hoff (Mem. de l'Academie Royale des Sciences de Suède, Stockholm, 1886). The simplest of these laws states that the freezing-point of a solution varies as the number of molecules dissolved in a constant quantity of the solution. The more concentrated the solution, the lower the freezing-point. The more salt added to ice, the lower the temperature of the mixture. As urine is a solution of various kinds of molecules, organic and inorganic, its freezing-point varies with the number of molecules dissolved in it, and as the diseased kidney excretes fewer molecules of certain constituents, *e. g.* urea, the freezing-point of the urine in a case of nephritis will be higher, *i. e.* nearer to zero than that of a normal urine. The greater the deficiency in excretion, the further away from the normal; the higher will be the freezing-point. In other words, cryoscopy is said to show the functional value of the kidney as an excretory organ.

While even Raoult and Van t'Hoff's laws suffer exceptions on account of ionization, *i. e.* the splitting of molecules into their constituent ions, each of which acts on the freezing-point as an independent molecule, lowering it proportionately to the number of ions instead of to the number of molecules, yet this is a comparatively negligible discrepancy. The chief point of contention as regards the theoretical basis of cryoscopy lies in the province of the physiology of the kidney.

Koranyi (*Zeitschrift für klinische Medicin*, 1897-98) sought in his theory of renal secretion to reconcile the theory of Ludwig (Mechanismus der Harnsecretion, Marburg, 1843), who regards the kidney as a simple filter, and that of Haidenhain (*Arch. f. d. ges. Physiol.*, 1879, IX), who considers the kidney purely as an excretory gland. Koranyi agrees with Haidenhain as regards the supposition that water and sodium chloride are filtered by the glomeruli, while the epithelium of the tubules secretes the other urinary constituents, but he also admits with Ludwig, that the sodium chloride solution filtered out of the blood by the glomeruli is in part reabsorbed by the canalicular epithelium. At the level of the canalicular epithelium, which acts as an excreting surface, as well as a living osmotic membrane, there takes place, according to Koranyi, an exchange which results in the final excretory product—the urine. The blood is separated from the salt solution which has filtered into the tubules through the glomeruli only by a layer of tubular epithelium, The blood outside the tubule and the salt solution inside of it are in a condition of perfect equilibrium as regards osmotic tension, and, according to the laws of osmosis, a diffusion of one fluid into the other takes place in such a manner that for each molecule of urea or other metabolic products that passes out of the blood into the tubule, there passes one molecule of sodium chloride from the tubule back into the blood. The number of molecules dissolved at any one time in the tubular contents and in the blood is therefore always the same.

While disputable and disputed in some minor features, this theory of Koranyi, which forms the backbone of cryoscopy as applied to urine, reconciles most experimental findings of recent studies upon the osmotic pressure of urine and blood with older researches on the relative significance of glomeruli and tubules in the excretory function of the kidney. If the validity of Koranyi's theory be admitted, the then quality of a given urine depends, other things being equal, upon the integrity of the osmotic membrane—the tubular epithelium.

The solids in solution in urine may be divided into two groups—the inorganic group, which is represented by sodium chloride, and the metabolic group, represented by urea. The sodium chloride of the urine is, as physiology teaches us, not a product of metabolism, but a substance which is taken into the body and excreted as such, without entering into the permutations of atoms representing the metabolism of the body. Its acts simply as a solvent and vehicle. On the other hand, urea and its congeners are substances which are formed in the body as the result of the most important of all metabolic mutations—nitrogenous exchange. As the freezing-point of urine shows the comparative total number of molecules in the urine, the ration between the freezing-point and the factor indicating the amount of chlorides in the urine shows the comparative number of metabolic molecules in the urine. When this ratio is normal the tubular epithelium and the glomeruli are, or ought to be, according to Koranyi, normal in structure and function. When, on the other hand, the number of chloride-molecules is in excess, the tubular epithelium is presumably diseased and incapable of excreting the normal amount of urea, while, when metabolic molecules are in excess, the glomeruli are presumably diseased not being able to filter enough salt solution to balance accounts with the urea.

While a number of authors, such as Claude and Balthazard, Casper and Richter, Bouinevitch, etc., have added clinical and experimental evidence in favor of Koranyi's hypothesis, another set of observers, equally trustworthy, have recently brought forth evidence apparently contraverting the ingenious story of the Hungarian savant. Thus, for example, Ascoli (quoted by Maragliano, *Gazzetta degli Ospedali e delle Cliniche*, March 23, 1902) studied a case of diabetes insipidus during the past year in which he could not find a balance of exchange between the chloride-molecules and the metabolic molecules. His findings were not only divergent from those of Koranyi and his followers, but were directly negative. In the same clinic, De Grazia not long since also investigated the experimental basis of Koranyi's hypothesis, and concluded that "the figures obtained, if considered in the light of Koranyi's theory, would show that lesions exist in healthy individuals," and that the elimination of metabolic products is not always in proportion to the freezing-point of the urine, nor to its contents of sodium chloride molecules.

A third research, which leads to conclusions that tend to impair the stability of Koranyi's theory, is that of Waldvogel (*Archiv für exper. Pathol. u. Pharmakol.*, XLVI, 1-2), who concludes as follows: "The theory that a molecule exchange goes on in the tubules between the molecules of chlorides and the excretory substances has no basis whatever. The ratio between the freezing-point of urine and that of water containing the percentage of chloride found analytically in this urine is not at all constant in nephritis. Besides, the same oscillations in this ratio may be observed in a variety of conditions of the kidney which have nothing to do with nephritis, *e. g.* compensatory hypertrophy of one kidney when the other is removed by operation. Finally, bloodletting and the injection of saline solution do not counteract the tendency of the urine of uræmics to show a high freezing point.

The three researches mentioned have as yet not been refuted, and it remains for further investigation to establish the true status of Koranyi's theory of renal function. Until then the question of the value of cryoscopy must remain unsettled. The subject is one of grave importance, as cryoscopy promises to become one of the most valuable aids to diagnosis in renal diseases, medical as well as surgical.

The Ambulance Surgeon.

While in some hospitals the ambulance work is assigned to the men who have been on the staff for six months, there are many hospitals in which this work is done by the juniors. In case a junior has never "substituted" on a hospital house staff, he comes to the responsible post of ambulance surgeon with little or no previous training. Ordinarily his college work has given him some skill in diagnosis and in the treatment of emergency cases, so that it is merely a matter of weeks before he has something of the technical facility of the experienced ambulance surgeon. Still the position of officer of a hospital is for him quite novel, and in his attention to the details of his cases he may overlook his proper relations to the public.

Of course, whether the hospital be a public or a private institution, its avowed purpose is the relief of suffering and the aid of the injured. This aim implies an attitude of ready sympathy with distress and a desire to be of service to those who may need the offices of a physician. The ambulance surgeon should accordingly so conduct himself that the by-stander shall not receive a false impression of his indifference to apparent suffering. His opinion, as one who is trained in the observation of disease, may differ entirely from the superficial ideas of the untrained onlooker, and yet he should not produce upon the mind of the casual eye-witness of his treatment an impression of carelessness or levity. Such unfortunate impressions tend to the injury of the hospital and the profession and indirectly of the public itself.

Toward the "man in the street" who in his interest forgets the proprieties of the occasion and annoys or interferes with the surgeon's work, his attitude should be quite impersonal. He should, as an officer of the hospital, not consider personal anything said to him and he should not resent as reflecting upon his own honor anything said in the foolishness of ignorance or hysteria.

Finally, it must be said that the relation of the hospital to the patient is essentially the same as that of a physician to his patient; and that in consequence the ambulance surgeon, its officer, is always to consider himself the guardian of his patient's interests. From this it follows that he should approach his work not from the standpoint of one who dispenses charity and is afraid of being imposed upon; but, with larger charity, he should have an eye single to his patient's best welfare, the hospital's supreme purpose.

The conduct of an ambulance surgeon should thus be always guided by the principles of sympathy, dignity, and professional duty, considerations that are perhaps obvious but too often forgotten in careless haste. We call attention to them not so much by way of reflection upon the character of the average ambulance surgeon, but rather because of that character, feeling confident that if they are brought to his attention during the first weeks of his service, these ideals will be carefully considered, and in most cases conscientiously adopted.

Tuberculosis and Public Action.

Dr. Alfred Hillier, an English medical practitioner, who has spent a large part of his life in South Africa, and who has interested himself greatly in all problems appertaining to tuberculosis, writes in the *Fortnightly Review* of April on "Tuberculosis and Public Action."

The writer finds that the primary necessity for public action arises from the fact that effective sanitation is the fundamental and principal means of prevention of tuberculosis. He shows that smallpox, leprosy, and the pestilences which devastated Europe in the Dark Ages were almost wholly due to uncleanliness, and demonstrates how these diseases have been controlled and, in some instances, extirpated, by cleanly methods of management of cities and dwellings.

The decline in tuberculosis has been enormous since 1835, and Dr. Hillier, referring to this, says "Let us consider more exactly what that decline has been, and endeavor, in the light of history and modern research, to understand its causes. From a death rate from tuberculosis of 3,800 per million in 1838 to one of 1,305 in 1896 the drop is a great one. The decline has not, however, been a perfectly regular one. The first striking fall in the death rate occurred in the decade from 1840 to 1850, which was about the time serious attention began to be given to sanitary reforms, and especially to land drainage. The rate continued to fall more gradually after this, till 1867, from which time forward it has been fairly continuous. It is during this latter period that nearly all the great sanitary works have been carried out in England. To these measures, to the improved condition of living and of working in factories, to better food among the working classes, and, most of all, to the improved housing which has been introduced in most of our great cities, there can be little doubt that the fall in the tuberculous death rate is chiefly due. In other words, the soil, though far from being rendered sterile to tuberculosis, has been, through the improvement in man's physical environment, rendered considerably less favorable to the growth of the seed."

Dr. Hillier concludes his article with this advice, "The vast majority of tuberculous cases are those in which the tubercle bacilli have been conveyed from man to man. On the appreciation of this main fact all intelligent preventive action must be based. Inasmuch as public opinion and public action are essential to the prosecution of this work, it is obvious that congresses, such as those held in Berlin, Naples, and London, serve a good and useful public as well as scientific end."

Good housing and efficient sanitation is the key of the situation in dealing with tuberculosis, and unless public opinion becomes aroused to this necessity, no great headway will be made toward prevention. The American public, and especially the New York public, have disregarded this aspect of the case, and needs to be thoroughly awakened to the danger of permitting a large portion of its population to exist in unhealthy environments. When this day dawns, the hardest blow will have been struck against tuberculosis.

Hydrotherapy in Tuberculosis.

Dr. Myer Solis-Cohen of Philadelphia is contributing to *The Trained Nurse* a series of lectures delivered by him before the nurses of the Jewish Hospital in Philadelphia.

In the course of his remarks he makes mention of the uses of water in the treatment of consumption.

The beneficial effects of the ingestion of water in disease has not, perhaps, received the praise that is, undoubtedly, its due. In tuberculosis the uses of water are manifold, and as a remedial agent it frequently surpasses all expectations.

Dr. Solis-Cohen speaks thus on the subject, "The ingestion of large amounts of water will assist in eliminating the toxins, while the drinking of hot water an hour or so before meals has the additional effect of keeping the digestive tract clean of facilitating secretion. The external application of water in consumption varies with the stage of the process and the condition of the patient.

In the first stage, that of lessened vital energy, hydrotherapy is employed for its hardening effects. It improves innervation, invigorates the circulation, and educates the vessels to resist changes of weather, stimulates nutrition, and acts as a respiratory tonic.

In the stages of pulmonary tuberculosis following the invasion of the tubercle bacillus, with destructive changes in the lung.

Hydrotherapy is of great value. The curative process in the lungs depends in large measure upon the active circulation of this organ. These hydriatic measures induce active hyperæmia. They strengthen the circulation, remove the circulatory weakness in the lungs, and the obstruction of the lesser circulation, and improve the flow of blood through the lungs."

Pure Milk for Brooklyn.

The milk supplied to Brooklyn is not giving satisfaction, and the King's County Medical Society and affiliated medical societies of the borough have resolved to endeavor to secure a comparatively good milk supply. Such milk will be certified and labelled as to its quality, so that purchasers will be able to place a reasonable amount of reliance upon its purity. A guarantee will be given that the milk does not contain more than thirty thousand bacteria to a cubic centimeter.

Brooklyn milk examined recently in the Hoagland laboratory revealed the fact that much of it is bad, one specimen of fifteen drops being found to contain as high as 43,000,000 bacteria. The object of the Brooklyn physicians is to be enabled to obtain sufficient good milk to prescribe to their patients. Of course, a milk of this description will cost more than the ordinary article, and that containing the label of the medical society probably twice as much. On this account the movement will, unfortunately, not benefit those most greatly in need of pure milk, the children of the tenements, for naturally the denizens of these regions will buy in the cheapest market, and consequently get the dirtiest and most inferior milk sold. The King's County Medical Society, however, is setting a good example by its action, and may assist in educating the poorer classes to a better knowledge of the need of a pure milk supply.

The New York Charity Associations.

Few, if any, cities of the world are more generous in aiding their poor than is New York. Money is poured forth lavishly in the attempt to better the condition of the indigent classes. Among the most prominent of the organizations to provide a needed change to the dwellers of crowded New York is the Children's Aid Society. This is one of the largest and most efficient of the New York associations which support summer homes for the poor children and endeavor to place permanently in country homes the little waifs who come under their charge. The large home of this society at Bath Beach accommodates thousands of children every summer, and excursions are made daily there in the hot season for the benefit of those who can only get a day's outing.

The Working Girls' Vacation Society is organized to give working girls in the city a chance to get a little rest and recreation in the country in summer, and to send those who have broken down under the strain of their labors to the Santa Clara home in the Adirondacks.

The St. John's Guild now supports a hospital in New York City, a hospital at New Dorp, and three floating hospitals, which daily carry the sick and weary mothers and children for short trips down the bay in hot weather. The passengers are also provided with wholesome food and milk, and hot and cold baths. Together, these hospital ships give some 50,000 people a chance to breathe salt air in July and August. The Gilbert A. Robertson home in Westchester gives whole families an opportunity to refresh themselves for a few weeks in the country.

The Association for the Improvement of the Poor has a place at Sea Breeze, L. I. The Edgewater Crèche near Fort Lee has one of the prettiest and best-equipped country playgrounds and recreation places for the poor in the country.

The above is by no means a complete list of the summer charity organizations of New York, but will serve to give a fairly accurate notion of the extent to which charity is distributed in the city.

The Charity Organization Society of New York and the Prevention of Tuberculosis.

A committee of the above society has been formed for the purpose of assisting in the prevention of tuberculosis. The members of the committee are Dr. E. L. Trudeau, Dr. Lederle, Commissioner of Health; the Hon. Homer Folks, head of the City's Department of Public Charities; Professor F. H. Giddings, the sociologist; there are besides many other well-known men, eleven of whom are physicians. The object of the committee is thus outlined by the Charity Organization Society.

Aside from the investigation into the social aspects of tuberculosis, the objects of the Committee have been formulated in part as follows:

1. The promulgation of the doctrine that tuberculosis is a communicable, preventable, and curable disease.
2. The dissemination of knowledge concerning the means and methods to be adopted for the prevention of tuberculosis.
3. The advancement of movements to provide special hospital, sanatorium, and dispensary facilities for consumptive adults and scrofulous and tuberculous children among the poor.
4. The initiation and encouragement of measures which tend to prevent the development of scrofulous and other forms of tuberculous disease.

There are said to be at least 20,000 consumptives in New York City alone, therefore, the formation of such a committee is fully justified by the situation. The social character of the disease has been greatly overlooked, owing to the fact that laboratory researches have almost wholly occupied the attention of scientists within recent years, to the consequent neglect of other causes. However, there are signs of a reaction against the germ theory run mad, and in the future it is likely that more common-sense views will prevail, and that while to bacteriology will be given all due honor and attention, the matter will be treated from other and just as important standpoints. The public require education with regard to tuberculosis, and the Committee will doubtless be the means of spreading enlightenment on the subject.

News of the Week.

An Appreciation of Lister.—The following editorial note, under the caption, "Long Live the King!" which appeared in the *Sun* of August 10, needs no comment:

"The coronation of Edward yesterday had a far broader significance than the crowning of a mere titular monarch.

"It was the coronation of modern antiseptic surgery.

"The Englishman on whose head the crown was placed in Westminster Abbey was really Joseph Lister—the head from which came the discoveries in the application of the antiseptic treatment by which the life of Edward and the lives of many thousands of other sufferers apparently doomed to death have been saved.

"Long live the King!"

A Quarantine Station at San Juan.—The President has recently placed Milaflores Island, in the harbor of San Juan, Porto Rico, under the control of the Public Health and Marine-Hospital Service for use as a quarantine station or site for a marine hospital, or both, as need may suggest.

The Belgian Society of Surgery.—The annual meeting of this society, held usually in June, will take place this year on Septemper 8, 9 and 10 at Brussels. The sessions will be devoted to a discussion of three topics:

(1) "The Treatment of Appendicitis," to be opened by A. Drs. Broca, Paris: A. Gallet, Brussels; C. Roux, Lausanne, and Sonnenburg, Berlin. (2) "The Treatment of Fractured Limbs," opened by Drs. A. Depage, Brussels; Rottschild, Frankfort, and Th. Tuffier, Paris. (3d) "Asepsis of the Hands, of the Operated Area, of Sutures and Ligature Material," opened by Dr. Walravens, Brussels.

The presence at the annual meeting of this Society of so many foreign surgeons has induced the members to lay the foundations of an International Society of Surgery, in ac-cordance with a proposition of the President. An invitation to this meeting has been sent to many prominent surgeons in every country. Those who have not yet answered the invitation are requested to do so without delay, addressing Ch. Willems, M.D., Chairman, or H. Verneuil, M.D., Secretary, Rue Royale 310, Brussels, Belgium.

Dr. Carl Gerhardt, an authority on pediatrics and also on pulmonary diseases, died on his estate of Damberg in Baden on July 21. He was one of the attendants of the Crown Prince Frederick and discovered the laryngeal growth to which his patient, then become German Emperor, succumbed. He was the editor of a handbook of Children's Diseases published in 1887.

Crusade against Malaria.—The New York Health Department has issued a circular for general distribution in the less thickly settled portion of the city, dealing with malaria and the means of its prevention. After a concise statement of the relation of anopheles to the spread of malaria, the circular continues: "To prevent malaria, therefore, we must either destroy the dangerous mosquitos or avoid their bites. In practice, both expedients are desirable. As the malarial mosquitos bite, as a rule, only at night, one will be usually safe by protecting his bedroom either with screens at the windows or a mosquito bar carefully arranged over the bed. Before going to bed one should kill all the mosquitos resting on the bedroom walls, in the closets or under articles of furniture, as the insects already in the room are most apt to give trouble. Moreover, all cases of malaria already developed must be carefully isolated under mosquito netting until pronounced by a competent physician to be cured. The other and still more important measure is to prevent the breeding of mosquitos in one's neighborhood. All mosquitos require standing water to lay their eggs in. To kill the mosquito larvæ, therefore, the rule is simple: No standing water. Where standing water must be had for washing or drinking, the top of the receptacle should be closely covered with wire gauze—not the smallest opening being left at the margin. When drainage cannot be made possible, the surface of the water should be covered with a film of kerosene oil. The oil may be poured on from a can or sprinkler. It will spread of itself. One ounce of oil to fifteen square feet of water is enough. The oil must be renewed about once a week during the mosquito season. Mosquitos do not fly far from their breeding places, and if all the householders in a given neighborhood will observe the simple rules given, experience has already amply proved that the results will be amazing. Persons keeping stagnant water on their premises are guilty of maintaining a nuisance, and it is the purpose of the department to proceed against all who neglect the warning of the department in this respect. Where large bodies of water, the drainage of which is too expensive for private enterprise, are in question, the department hopes to enlist the assistance of the proper city authorities, so that there need be no reason why the plague of mosquitos and malaria in the suburbs of New York should not be entirely removed. In order to make these recommendations effective, the city will be districted, and each district inspector will prepare a map, showing every pool or accumulation of stagnant water where the larvæ of the mosquito can grow. Richmond and Queens are already districted for this purpose, and action is taken by the department as fast as the reports of inspectors come in. The owner of each piece of property on which water is stagnant receives at once an order to abate the nuisance.

Complaints of British Transport Service.—Captain Shields, medical officer of a transport carrying returning troops from South Africa to Melbourne, has made a report in which he condemned the service in the strongest terms. He said that "the overcrowding of the ship was shameful and scandalous, and without consideration for health or loss of life. The air was poisonous and foul, and the decks were always wet, causing pleurisy and pneumonia." He said, further, that the supply of medicine on board was absurdly small, and that the condition of the ship was directly responsible for the epidemic and deaths on board.

A New Medical Journal.—The *Old Dominion Journal of Medicine and Surgery* is the name of a new periodical published at Richmond, and edited by Dr. Greer Baughman, assisted by Dr. A. B. Greiner. It is the official organ of the alumni society of the Medical College of Virginia.

News from Minneapolis.—Dr. William Asbury Hall, President of the Minnesota Medical Society, in an interesting address recently delivered before that society, gave utterance to the following curious statement: "The code of ethics of the American Medical Association is, in my opinion, a grand exposition of the principles of upright professional character, and it has been shown that those who oppose it are those who have never read it, or those who are governed by the spirit of commercialism. The spirit of commercialism caused the old New York State Medical Society to renounce it, and after a trial of eighteen years they have found that their action did not pay." We fear Dr. Hall has been misinformed as to the facts. We were not aware that the Medical Society of the State of New York was on the stool of repentance, but we are assured that the code of ethics of the American Medical Association is to be revised and amended. The news of this seems not yet to have reached the Falls of Minnehaha.

Dr. Florence Hull Watson, First Assistant Physician of the Delaware State Hospital at Farnhurst, formerly in charge of the Pathological Department of the State Hospital for the Insane at Norristown, Pa., has resigned to continue work in Europe.

The New Brunswick Medical Society.—The twenty-second annual meeting of the New Brunswick Medical Society was held in St. John on July 15 and 16. The attendance was the largest since 1895. The officers elected for the ensuing year were: *President*, Dr. G. A. B. Addy; *First Vice-President*, Dr. J. D. Lawson, St. Stephen; *Second Vice-President*, Dr. A. R. Myers, Moncton; *Treasurer*, Dr. G. G. Melvin; *Secretary*, Dr. J. H. Scammell; *Corresponding Secretary*, Dr. Clara Olding.

The American Association of Obstetricians and Gynecologists will hold its fifteenth annual meeting in the Convention Hall of the Hotel Raleigh, Washington, D. C., Tuesday, Wednesday, and Thursday, September 16, 17, and 18, 1902, under the presidency of Dr. Edwin Ricketts, of Cincinnati. The secretary, Dr. William Warren Potter, 284 Franklin Street, Buffalo, should be communicated with on all other subjects pertaining to the meeting. All physicians, and especially those in Washington and vicinity, are most cordially invited to the scientific sessions. The preliminary program contains the titles of forty-four papers.

A Wireless Ambulance Call.—While the *Kaiser Wilhelm der Grosse* was making her way to this port last week, one of the passengers was taken ill with symptoms of appendicitis. An operation was indicated, but as land was so near it was deemed advisable to wait until the ship arrived. Accordingly, a wireless message was sent while the boat was still fifty miles away, and in response to the call an ambulance was in waiting when the pier was reached. The patient, a son of former Prime Minister di Rudini of Italy, was taken to hospital, operated upon, and is now convalescent.

Cholera is spreading in Manchuria with alarming rapidity. The deaths at Kharbin, on the Eastern China Railway, number between 100 and 130 daily, chiefly Chinese. It is feared that the epidemic may reach Irkutsk and Vladivostock. The Russian sanitary precautions are wholly inadequate. A similiar report comes from Blagovestchensk, where between July 22 and August 3 there were 161 cases and 101 deaths, the medical resources being inadequate to cope with the epidemic. At Manila, on the other hand, the disease is rapidly subsiding since the temporary recrudescence of two weeks ago. Outside of Manila a total of 5,967 cases has been reported, with 4,290 deaths, since the epidemic began. In the city there have been 1,350 cases, with 1,100 deaths. The people in the small towns are very ignorant. They consider cholera a visitation of Providence and cannot be induced to take proper precautionary measures. Among those attacked have been two officers and sixty-two men in the army. Most of these cases occurred in Laguna and Batangas. The cause in the majority of instances was the drinking of infected water. A few cases were due to food, contaminated either by handling or by flies. In Samar and Loyto some cases are reported, but the disease has not spread widely. In the Camarinos Sur the epidemic seems to have been stamped out, but in Laguna and Batangas and the adjacent parts of the province of Tayabas, cholera has spread in virulent epidemic form, many case having occurred without report.

The International Congress for Improving the Condition of the Blind was opened in Brussels on August 6 under the patronage of the King of the Belgians and Duke Charles of Bavaria. There were many representatives at the Congress from the various European countries and elsewhere. The objects of the Congress were to examine into the best means of enabling the blind to gain a livelihood, and the methods of recreation adopted in various institutions, as well as the causes of blindness in populous centers and the best means of prevention.

The Board of Health on Public Baths.—A recent report to the Health Department, by Assistant Sanitary Superintendent Dillingham, says that investigation of the floating baths situated on the water front of this city shows that many of them are in an unsanitary condition, and are located near the mouths of adjacent sewers which cause the water to become contaminated with the sewerage. Previous investigation of the baths on the land show that many are kept in an unsanitary condition and that the water is not changed oftener than once or twice a week. These baths, Dr. Dillingham urges, should be directly under the supervision of the Department of Health, and he recommends that the Sanitary Code be amended to read that no baths be maintained in the city of New York or along the water front without a permit from the Board of Health.

Professor Albert von Kolliker, the anatomist, has resigned from the chair of anatomy at the University of Würzburg, which he occupied for fifty-five years. He is eighty-five years old, but still vigorous in mind and body.

The Leper Colony in Guam.—The Navy Department has received a report from Commander Schroeder, governor of the island of Guam, saying that the leper colony he proposed to establish would be ready for occupancy by July 1. It was supposed that the lepers had all disappeared from Guam, but investigation developed that many victims had been secreted by their friends in various parts of the island, and Commander Schroeder determined that they should be gathered in one place to prevent the spread of the disease.

The Colored Home and Hospital.—Permission has been granted this institution by the Supreme Court to change its corporate name on September 15th next, to the Lincoln Hospital and Home.

To Improve the Breed of Royalty.—A dispatch to a London news agency from Rome, probably manufactured for summer use, announces that the Pope has notified the Catholic reigning houses of Europe that no more dispensations for consanguineous marriages will be granted. It is the wish of the Pope, says the dispatch, that royal personages contract marriages outside of royal families in order to put a stop to the tendency to physical and mental decadency now so apparent. As there are but four thrones of any importance occupied by Catholics, the Pope's remarks, if he ever made them, might be regarded as somewhat personal.

A Muscular Surgeon.—Dr. Rorke, of St. Catherines Hospital, Williamsburg, was the other day on an ambulance with a patient in great straits, and in order to save a long detour attempted to drive through a street which was closed for repairs. There was room for the ambulance in the completed center of the street, but the foreman refused to remove the bar. Dr. Rorke then moved it himself and the foreman struck him, but was laid low by the surgeon, and the ambulance went on to the hospital. The law of necessity is superior to the law of street repairers.

An International Tuberculosis Congress.—An international conference on tuberculosis under the auspices of the Central International Office for the Prevention of Consumption, will be held in Berlin from Oct. 22 to 26. Each country has been notified of the approaching congress, and invited to send at least two delegates.

Obituary Notes.—Dr. BRUNELL of Montreal died suddenly in camp at Mountain View, N. Y., where he was passing the summer, on August 6. He was a graduate of the University of the Victoria College of Cobourg, Canada, in 1875.

Dr. HENRY DARLING of Washington died at his home at Brightwood, D. C., on August 7, aged fifty-eight years. He was a graduate of the University of Virginia, and of the medical department of the University of Maryland.

Dr. ERASMUS DARWIN BEACH, the oldest physcian in New Orleans, died there on August 6, aged eighty-seven. He was born near Cincinnati, was graduated in medicine at the Medical College of Ohio in 1842, went to New Orleans in 1846, and had practiced medicine for more than half a century.

Dr. JESSE BRADFORD LOSEY of Conesus Centre, Livingston County, died August 5, aged seventy-five years. Born at Dansville, N. Y., Dr. Losey was graduated from the medical college of the University of Vermont, and went to Conesus Centre, where he practiced his profession for more than forty years. During the civil war he served in the Twenty-second New York Cavalry, and rendered efficient services at the battles of the Wilderness and Malvern Hill.

Dr. ABNER M. MILLER died at Bird-in-Hand, Pa., on July 28, at the age of sixty-eight years. He was a graduate of the now-extinct Pennsylvania Medical College of Philadelphia, in the class of 1858.

Dr. J. AUBREY DAVIS died at Philadelphia on July 30 of meningitis complicating nephritis, at the age of thirty-seven years. He was graduated from the medical department of the University of Pennsylvania in 1887 and became a resident physician in the Philadelphia Hospital. Subsequently he was appointed a medical inspector of the Bureau of Health, continuing in this office until two years ago.

The Present Aspect of the Cancer Problem.—Roswell Park reiterates the fact to which he has more than once called attention, that there is no other disease characterized by progressive infiltration which has not a parasitic cause, or a parasite as a cause. He declares himself to be a most ardent advocate of the parasitic hypothesis. He describes a number of experiments by investigators which support this view. Czerny states that there is more reason for believing in the infectiousness of cancer than of leprosy. As to the relationship between cancer and tuberculosis, he says that one must admit that the tuberculous process is at least capable of acting as an irritation which, like any other continued irritation, may provoke epithelioma, while at the same time it probably also lowers local tissue resistance. Lubarsch found, by careful study of statistics, that from 4 to 5 per cent. of tuberculous patients suffer also from cancer, while about 20 per cent. of cancerous patients suffer from tuberculosis. These figures have been fairly confirmed by results obtained elsewhere by Zenker, Cordua, and Loeb.—*Medical Review of Reviews.*

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE KING'S CONVALESCENCE—REFORMING THE BRITISH MEDICAL ASSOCIATION—MIDWIVES' BILL—EGYPTIAN RESEARCH—THE ROYAL COLLEGES—CANCER RESEARCH—HOSPITAL FUNDS—OBITUARY NOTES—THE KING RECOVERING—CANCER RESEARCH—COLLEGES AND DEGREES OF LONDON UNIVERSITY ARMY MEDICAL MATTERS—HERBERT SPENCER ON VACCINATION—REGISTRAR-GENERAL—KING EDWARD'S HOSPITAL FUND—OBITUARY.

LONDON, July 18, 1902.

ON Tuesday the King was removed to Cowes, where he is enjoying the sea breezes and continues to progress rapidly. Could any case of the kind run a more satisfactory course? Of course, special arrangements had to be made for the journey, so that his Majesty might complete it in the recumbent position; but difficulties which would be insuperable for an ordinary patient were easily overcome for the King, and a bulletin was issued to say he had accomplished the journey without fatigue.

Residing on the royal yacht, the King has the full benefit of the sea, which he always enjoys. Each day his couch is carried on deck. His favorite spot is beside the great wheel on the quarter-deck, where he has a full view of the entire water-front from the pier at East Cowes to the castle of the Royal Yacht Squadron.

The weather has been favorable, though sometimes oppressively warm, but the royal invalid has not suffered from the heat. The wound is healing steadily, if somewhat slowly, and there has been no setback of any kind. Comfortable nights, with sound sleep, have been passed, the appetite has continued to be natural and the diet has now been increased and more varied. Altogether, the convalescence is uninterrupted and the condition of the King will no doubt be improved by the further rest and restricted diet which such a case necessitates, as well as from the freedom from social engagements and state cares. He has been able to give various audiences and to attend to the business involved in the change of ministers without fatigue. In fact, to the physician's eye, he looks better than for a long time preceding his illness. In view of this satisfactory progress the coronation has been provisionally fixed for the 9th of August, and the fleet is to assemble for a review in the following week.

At the approaching meeting of the British Medical Association the scheme for reorganization has to be submitted for final approval, and it seems likely that the discontent of some members will lead to lively discussion. The scheme has been worked at with much patience by the committee appointed to draw it up, and has been approved by many branches and at special general meetings.

But the malcontents say, "What are eighty-three votes out of thousands who could not attend?" Dr. Glover, who usually speaks with moderation, was moved to pronounce the new rules "fantastic, new-fangled, costly, and altogether degrading," and declared they would "add immensely to the combinations of the association and impose another set of masters on the executive."

That is a tolerably severe communication, but there are others who go further in their expressions of disapproval. It is a grievance with some that a good deal of money, they say about £2,000, has been expended on the elaboration of the scheme, and certainly much valuable time has been devoted to it by earnest reformers. A proposal to increase the subscription by four shillings per annum seems to irritate a good many, and others are specially annoyed that they are to be compelled to belong to a branch—many members having always been "unattached" to the local branches.

Apart from such minor objections, there is no doubt that the scheme involves a great dislocation of the existing organization, so that there is plenty of room for differences of opinion, and such differences were vigorously expressed at the meeting on the 9th inst.

Sir Victor Horsley and Mr. Whitaker, who have taken a large share in preparing the scheme, strongly urged its acceptance. Dr. Glover, who had previously offered no opinion, led off the opposition, and was seconded by Dr. Brassey Brierley, who has actively opposed it all along. The proposal to expend large sums on delegates who are bound to vote as directed in resolutions of their constituents was pronounced wasteful and useless, as the resolutions could, without cost, be inserted in the *Journal*. Annoyance was also expressed that with this meeting, called for two o'clock, a council meeting should also have been called for three o'clock, as if the old tactics of the wire-pullers had been resumed with a view to hustling the general meeting

The Midwives' Bill has passed the Lords with slight amendments, and, for good or evil, we must now abide by it. The apathy of the profession has allowed a new order to be organized and has retained practically no control over it. The Medical Council is, indeed, to have the regulations of the Midwives' Board submitted to it for consideration, but the Privy Council need not follow its advice. Perhaps this may be no great loss, for the Council has all along failed to appreciate the efforts of the new competition. The main purpose appears, at first, simply to register midwives so as to distinguish qualified from unqualified. But a period of grace of eight years is allowed for any one to obtain a certificate, and in the meantime to practise without one The tendency of the new order will, in time, lead to the claim to be the principal or even sole practitioners of midwifery, and yet these women are only to have a short training in this branch. Thus the medical acts which required practitioners to be qualified in medicine, surgery, and midwifery, are to this extent set aside and partial qualifications recognized for women. At the same time, the medical assistant who has completed his hospital curriculum, but has not obtained a diploma, is left in his anomalous position, and cannot attend a case except under the supervision of his principal. The women have, indeed, scored a triumph, but whether for the public good may be well doubted.

A very interesting exhibition has been held at University College, representing the Egyptian research of the year, carried out by Professor Flinders Petrie and Drs. Grenfell and Hunt. Their explorations seem to connect prehistoric with historic times, the objects showing continuity from the last stages of the prehistoric age to the period of the royal tombs.

Some of the most interesting finds are manuscripts. Old letters, bills, receipts, etc., seem to have been used to stuff animals that were to be preserved, and some of these papyri have been deciphered. Mummies of men, children and animals, with many toys, personal ornaments, portraits on wood, statues, etc., already explored, have been brought over from the tombs. Perhaps the most striking object in the collection is a "Panama hat" which is not Panama, having been made so many centuries before the discovery of the New World, though its texture is equal to the finest example of modern workmanship.

The College of Physicians has a sum of over £100 remaining from preparations for the coronation. This is to be put aside as a nucleus of a fund for a portrait of the King (honory fellow of the College). At the annual meeting of the fellows of the College of Surgeons for the sixth time, there was no quorum.

The two colleges have let a part of their joint laboratories to the Army Medical Department for three years at the substantial rent of £1,050 per annum.

The Cancer Research scheme of the colleges has been approved by both. It will encourage and assist cancer research in the British Empire and provide for systematic investigation into the causes, prevention, and treatment of the disease.

The Hospital Sunday Fund now exceeds £45,000, and some returns have yet to be forwarded. There is no hope of the amount reaching much over £60,000, even if that amount be secured.

St. Thomas's Hospital will benefit under the will of the late Charles Gassiot by about a quarter of a million sterling.

Mr. Chamberlain's wound healed well, and he has resumed his work.

Dr. Alexander Marsden died on the 2d instant, aged seventy years. His father, Dr. William Marsden, founded the Cancer and the Royal Free Hospitals. These institutions have also enjoyed a large proportion of the work of the son. He was on the committees of management, a trustee surgeon, and later consulting surgeon to each In his early days he served in the army, was in the Crimea. at work in the trenches, and one of the first to enter Sepastopol.

The death is also announced of Dr. H. T. Parker, Principal Medical Officer of the Prisons Department, Cairo. He was M.D., B.S., Lond. D. P. H., etc., and only thirty-three years of age.

Another young physician of great promise was Dr. E. de la Fosse Bond, an Oxford graduate, who died at the Fever Hospital on the 1st instant, from scarlet fever contracted in the course of his duties. He was only twenty-eight years old, had had a distinguished career at the University, and was very highly esteemed by his many friends.

LONDON, July 25, 1902.

"THE King continues to make uninterrupted progress." That is the opening statement of yesterday's bulletin, which goes on to say that "although he is not yet able to leave his couch, his strength is returning satisfactorily." Only two bulletins are now issued in the week, a fact which of itself is significant of good progress. Granulation is going on well and the general health is all that can be desired. His Majesty's couch is wheeled on deck whenever the weather permits, and it has permitted it on most days this week. Yesterday it was expected a short cruise might be taken, but the Royal yacht did not leave her moorings. Preparations for the coronation on the 9th prox. are being actively pushed forward.

The Middlesex Hospital is taking advantage of the interest aroused in cancer research to appeal for funds to reinforce the work done in their own cancer department. This department was founded more than a century ago with the twofold object of providing for cancerous patients and to investigate the nature and cause of the disease. Forty-five beds are maintained for advanced cases and many others are treated in the wards or as out-patients. About two and a half years ago a new wing was built and equipped and further provision made for laboratory research. The work is well organized, and for more than two years has been under the direction of Mr. A. G. R. Foulerton. A report on this work is in the press. There is an opportunity of extending the laboratory accommodations and increasing the staff, and the managers ask for subscriptions of some £2,000 a year for about ten years to enable them to take full advantage of that opportunity. Toward that sum the governors have already been promised upward of £700 a year, chiefly through the instrumentality of Mr. Pearce Gould, who is surgeon to the hospital. The work proposed to be done does not conflict with the scheme which is being organized by the two Royal Colleges of which I have already given you some account. The fact that the hospital provides so much clinical material for study, and that its staff will work hand in hand with the laboratory staff, distinguishes the cancer department of the Middlesex Hospital, and I should hope that their appeal for funds will be well responded to.

Sir H. G. Howse has been re-elected President of the Royal College of Surgeons. He stated at the quarterly meeting of the Council, on the 10th inst., that at the next meeting a report would be submitted by the committee appointed to receive a deputation from the association of members and licentiates of the two colleges. These gentlemen are anxious that as holders of the double qualification the colleges should endeavor to effect some kind of combination with the newly constructed University of London, so that they might have the degree of doctor. There is a good deal of force in the contention that the double qualification of the colleges, is just as good, so far as examinations go, as the university degree. Yet the doubly qualified gentlemen cannot call themselves "doctor." It is one of the results of the variety of our qualifications. We have licentiates, members and fellows of colleges on the one hand; on the other, bachelors and doctors of the universities. The former think that the title of doctor gives an advantage with the public which is not deserved, and, as their cirriculum is concluded, they cannot even present themselves for examination at a university for the doctorate. The London University, which has been hitherto merely an examining board, has so arranged its regulations that only students who knew all about it and determined at the outset, could obtain its degrees. A qualified practitioner, who wanted to take its degree, would have to begin his cirriculum over again, as no study would be recognized until after the preliminary examination had been passed. One or two men have gone back to their school studies and passed the preliminary and then gone over their hospital career again—more or less perfunctorily. But it is impossible for many to do this, and it is by such regulations and excessive examinations that the university tried to make its degrees esteemed. That is the chief reason why some of the greatest of our medical leaders were never graduates of London. Now that Latin as well as Greek is to be dispensed with, it would seem reasonable to admit to examination men whose education is complete.

It may interest you to hear that Sir William Taylor, Director-General of the Army Medical Department, is inclined to follow the example of some foreign services by issuing a journal. He has inquired by a circular the opinion of his officers by way of estimating the support that might be reckoned on. There are many officers, I believe, who would be glad to contribute valuable papers. Not a few such papers have been, so to say, buried in the blue books of the department, and remain practically unknown except to the few who carefully read their appendices to the annual reports. Of course, if properly edited, the new journal would contain full information on all subjects connected with military surgery, medicine and hygiene, and would keep up the interest of officers in the general progress of medical science.

I would suggest that it would be as well to include the Sister service and so produce a journal which should represent the scientific and practical work of both the military and naval services.

The recent examinations for the army medical service was really competitive, over seventy candidates coming forward for thirty-two places.

There is no further announcement as to the great Netley School. The establishment of the Medical Staff College in London must render it unnecessary to keep up the school at Netley, although the hospital will remain. Perhaps the professors will be transferred to London, a plan which would secure continuity in the work. Earl Roberts is to distribute the prizes on Tuesday next. Perhaps he will make some announcement.
